Experiment is continually bringing to nought the ysiology which calls itself classic. When the mortal Harvey demonstrated by decisive experints the circulation of the blood, he upset the classical ysiology of Galen, of Hippocrates and of Aristotle, d aroused the ire of the professors for 20 years. hen Lavoisier showed that life is a chemical enomenon of combustion, he demolished the hazy eas of Stahl and of Willis. When Claude Bernard scovered that the animal organism can manufacture gar, he had against him all the doctors and all the ysiologists. When Pasteur developed the microbial eory of infection he met with formidable opposition. l these men were thus revolutionaries simply cause they had faith in the experimental method, d rejected the popular ideas, the prejudices, the eories and conceptions of their orthodox and stinate colleagues, which were not in accordance th facts, and which were not guided by experiment d observation, both methods equally indispensable the search for truth. I do not claim to rival these r masters, but only to follow the way which they ve led.

The subject of my discourse to-day is very revolunary, and I expect to meet with severe criticism. ıt I would say, in the words of Themistocles: Strike, but listen." Before judging me, hear what ave to say.

The New Science and its Forerunners.

The thesis which I wish to sustain and to prove by experimental method is that there may be a owledge of reality obtained by other means than the ordinary channels of the senses. Everyone ows that the external world is accessible to us by r senses, by vision, hearing, and touch, and to a s extent by smell and taste. No other ways are own. It is the universal opinion that we can have other notion of the reality that surrounds us except ough our five senses, and that any fact must remain ever unknown unless sight, touch, or vision has revealed it to us. This is the classic and at the same time popular idea. It is formal and exclusive, without itself ever having been demonstrated. To admit that a knowledge of occurrences can arrive at our consciousness by any other means than those of the senses, is a daring and revolutionary proceeding, and yet this is the thesis that I am about to maintain.

I am, however, not alone in defending this position. I have precursors and supporters, especially among English men of science. In the first place I would mention Frederick Myers, of Cambridge, one of the most trustworthy and intelligent men that I have ever known; my illustrious friend, Sir Oliver Lodge, Sir William Barrett, the renowned William James, Mr. and Mrs. Sidgwick, the great Cesar Lombroso, my friends Ochowitz, Flammarion, A. de Rochas, Geley, J. Maxwell, as well as the professors Bottazzi, Foa of Padua, Morselli of Genoa, Schrenck-Notzing of Munich, Herlitzka of Turin, all eminent physiologists, as well as many others whom I cannot enumerate here. I am thus not in bad company, and this fact may give me heart of grace to proceed. Indeed, we have not the right to reject summarily the mature opinion of these thinkers, who have all been scrupulous and painstaking experimenters. But I shall not appeal to their authority, nor say: *magister dixit.* I shall rely only upon observation and experiment.

I have tried to find a name for this new science, which though a chapter of physiology, does not make use of its ordinary technique. Just as Aristotle called the science which was beyond physics, metaphysics, so I propose to call this science which goes beyond the ordinary psycho-physiology, metapsychics. I have divided it into two distinct groups—namely, (1) subjective metapsychics, which deals only with the phenomena of consciousness, and (2) objective metapsychics, dealing with the external phenomena which are not explicable by the ordinary laws of mechanics.

To-day I shall not say anything about objective metapsychics and shall confine myself to the psychological phenomena, not wishing to administer to you too strong a dose of revolutionary poison. And even in speaking of subjective metapsychics, I shall say nothing of that strange phenomenon which clashes so violently with all our notions of moral liberty—i.e., premonition, revelation of events which will occur in the future. Though I have a firm belief that such cases of premonition do occur, I shall to-day confine myself to the attempt to convince you that a knowledge of the real world can arrive in consciousness in other ways than through the ordinary channels of the senses. The audacity of my thesis will be sufficient excuse for such limitation of my subject.

Facts of Observation.

As in the study of any other physiological phenomenon, we can proceed by two methods, by observation and experiment. Observation is less fruitful and less demonstrative than experiment. We dare not, however, neglect it. Facts of observation arrive unexpectedly. They cannot be foreseen, nor be dealt with in persons hypnotised or specially sensitive. Ordinary common-sense is sufficient to show that they cannot be explained by mere chance.

The following case is remarkable, not only in itself, but also because it was observed by one of the masters of modern thought, William James.

A young girl, named Bertha, in New Hampshire, disappeared, and it was thought that she was drowned in a neighbouring lake. Repeated search at the bridge and in the lake gave no result. Two days afterwards, Mrs. Titus, an acquaintance of William James, who lived 8 kilometres away, dreamt that she had seen the body of Bertha in the lake at a spot which she localised accurately. A diver descended at this spot and found the body. More than a hundred people had been looking in vain for the body for two days.

Mrs. Green, of London, dreamt that she saw two women whom she did not recognise in a little carriage, and that the horse fell into the water, that two hats floated to the surface, and that the two women were drowned. On awaking, she described her dream. Now at this very moment, at the same hour allowing for the difference of longitude, a niece of Mrs. Green, whom her aunt did not know, in Australia, went for a drive with a friend and was drowned. The two bodies were found, the hats were floating on the surface of the water. The details, which are well authenticated, are so numerous and precise that the law of probability would show enormous odds against such a dream being a mere coincidence.

But of course one cannot raise an edifice on a single stone. There are hundreds of similar cases, and it is especially the English workers who have collected them with zeal and patience.

Mr. Wingfield, on waking on his yacht, sees his brother appear in his cabin, pale and sad. Much frightened, he goes into another cabin and writes in his diary his brother's initials, followed by "God forbid," and the date and hour of the apparition. At the same hour his brother, Richard Baker, was killed while hunting in England by a fall from his horse.

Mr. Smith, employed at a bank in London, comes home after dinner and is talking quietly with his wife. Suddenly he stops and says: "What time is it?" "It is 8.45." "Very well, then Fred has died at 8.45. I have just seen him." It was found that Fred had died exactly at this minute.

Victor Hugo, in his "Choses Vues," relates a similar instance. Mme. Guérin says to her daughter: "I have just seen Mme. Lann pass; she died an hour ago." And it was correct. Mme. Lann had not been at all ill.

Four Possible Explanations.

I could quote a much larger number of similar occurrences, and it seems to me that they are demonstrative. Nevertheless we must discuss them. Four explanations are possible.

1. We might be dealing with defective or fraudulent observations. Now in the larger number of these cases the hypothesis of fraud is inadmissible. Out of the hundred which I might quote there has not been a single one where there has been deliberate falsehood; but their record may have been incomplete and inexact, and this is indeed probable, since in spite of all precautions certain facts have been reported inexactly. If we admit, to be extremely strict, that half of these cases have been inexact, and even with an exaggerated severity we exclude them altogether, there will still remain 50 of which the accuracy cannot be disputed.

2. The second hypothesis is that chance will account for all. Chance is, indeed, a very convenient god, to which we can always appeal. But why should we introduce these extremely small probabilities into our calculations? Practically we never come across a probability of 1 to 100 million, and yet this is the figure at which one must assess the probability of Wingfield having once in the course of his life a single hallucination, and that just the hallucination of his brother being killed at the same moment. Chance will evidently not explain these occurrences.

3. The spiritualists have adopted a much simpler explanation—that the astral body of a dead man returns. Such an explanation does not satisfy me, since many trivial warnings occur, in which there is no question of a death, and because it is generally, if not always, subjective, the phantom being seen only by a single person. Above all, physiology teaches us explicitly that all thought disappears with the death of the brain. Anæmia, asphyxia, intoxication, concussion, and compression of the brain interrupt its activity to such an extent that it is almost impossible for any physiologist to admit that any personality or consciousness can exist when the brain has ceased to function.

4. The fourth proposition is neither an explanation nor an hypothesis but is a simple enunciation of the fact, which is confirmed in a startling manner by experiment, that the occurrences of the external world, even when they do not affect our sense organs, can still influence our consciousness. By what channels I do not know, but the fact is there. Reality comes to us and then the knowledge of this reality takes a symbolic form, as in a dream. The unconscious part of Mme. Guérin is warned that Mme. Lann is dead, and in order to bring this fact to the conscious personality of Mme. Guérin her unconscious se imagines a dream. Hence comes the innumerabl variety of these symbolic dreams, which all tend t the same result—a knowledge of reality, even thoug this knowledge arrives by mysterious and unknow channels.

But however important these observations, whic would suffice alone by their number and precision t make us admit that we are endowed with a hidde form of sensibility, which I call *cryptæsthesia*, there a whole mass of still stronger evidence to demonstrat its existence. It is true that one cannot bring a observation into existence, but one may provoke i Now, an observation that has been provoked, what that but an experiment?

The Experimental Data.

We may consider the experimental data under tw heads: (1) those observed in persons in the hypnoti state or in the so-called spiritualistic trance, (2) tho which have been observed in normal individual Both sets of experiments are equally valid and lea us to the conclusion that, in addition to ordinar sensation, there exists a mysterious hidden sensibilit —a *cryptæsthesia*.

In Hypnotised Individuals and Mediums.

In the first place, in hypnotised individuals or i mediums we obtain unmistakable proofs of clai voyance. I will here record certain experiment which are known to me personally.

Alice has never seen Dr. Héricourt and has never been i his house. Héricourt gives me a drawing enclosed in a envelope carefully sealed. The drawing represents a fra in which he can put a photograph. Now Alice says to me "I see a man—a soldier, with a képi and three stripes on th képi." That was exactly the photograph contained in th frame when Héricourt was drawing the frame alone. Ju think of the number of things that Alice might have said a circle, a cross, a bridge, a sheep, a gun, a horse, a farm in fact, quite a dictionary, and you must acknowledge tha the probability of her saying a soldier with three stripes o his képi was infinitesimal.

My pupil and friend Langlois, whose death three wee ago we deplore, was making an experiment with me in th laboratory. In the evening I asked Léonie, who was at tha time the only person beside myself in my house and who cou not have seen anyone coming from the laboratory: "Wha has happened to Mr. Langlois?" She replied to m brusquely: "He has burnt his hand with a red liqu Why does he not take care when he is pouring it out? T skin was blistered at once." As a fact, Langlois, in preparin a solution of hypobromite of soda, had spilt a pretty lar quantity of bromine on his arm, causing a severe burn.

With Stella I have had convincing results in experimen with one of my friends, G., a clever and sceptical physicia Stella knew neither him nor his family. He asked he "What is the name of my son?" Stella, by means of th table, which he was not touching, replied: "Jean," an added "rit voiture." Now G. had given to his youn son a carriage, with which the child was greatly amuse G. asked again: "What is the name of a brother whom have lost?" Reply: "André." G. said "No," an thereupon Stella said: "André, il vit." Now G. has brother living who is named André.

I gave to Miss Thompson, in presence of F. Myers, m eldest son's watch. Miss Thompson said at once that the was blood on this watch, and she added these words, su prisingly exact: "Three generations mixed." This wat had belonged to an uncle of my son, George, who had be killed in 1870 at Vendome. His father had recovered th watch and had presented it to his grandson, my son Georg Of course, Miss Thompson was ignorant of all the details.

The most striking of all the facts of cryptæsthesi is perhaps the following. In June, 1906, at 10.30 P.M in the presence of two of my friends, Mme. R., b means of table-raps, gets the message: "Banca la mort guette famille." But no one present kne Bianca, for I imagined that Banca stood for Bianc The next day, at 2 P.M., the news arrived at Par of the cowardly assassination of Draga, the Quee of Serbia. At the time I saw no relation betwee

---

[1] Or rather Pandja. The dj is a letter peculiar to th Serbian alphabet.

his occurrence and the words given by the raps, but he next day I read in the papers that the father of)raga was called Panca. Without insisting on the etails of this extraordinary occurrence, I will only ay (1) it was impossible for anyone present to know nything of Serbian affairs, and they were totally nacquainted with the names of Draga and her ather; (2) the coincidence of the time is exact to the iinute, 10.30 at Paris corresponding to midnight at ‹elgrade. The warning was given at the very ioment when the officers left their hotel to go and iurder Draga and her two brothers; (3) "la mort uette famille" expresses with amazing precision he blow which was about to strike the family of ‹anca; (4) the family was sufficiently eminent to e able to establish the authenticity of the warning. f in the whole world death was threatening three ersons in any one of 20 families, I could have heard othing of it if it had not been a princely family.

I have tried to calculate the probability of this onderful warning. For the word Panca, it is pproximately $(1/25)^5 \times 1/7$, but for the words "la iort guette famille," the probability is still smaller nd is only about $(1/10)^{10}$. But what does it matter there are two or three noughts more or less? This finitesimal probability gives us a moral if not a iathematical certainty that mere chance can have othing to do with it.

Mrs Piper.

I come now to experiments made by various ıvants on Mrs. Piper. She is an American who has iven the best examples of clairvoyance that I have ver known. Since three thick volumes of them have een published, it is evident that I could only give ere a very meagre summary, and I shall confine ıyself to mentioning the conclusions of the eminent ıen who have questioned and studied Mrs. Piper.

Richard Hodgson, very sceptical, who had already ıade an inquiry in India in order to control the ssertions of Mme. Blavatsky and had concluded that ıere was fraud involved, studied Mrs. Piper for ur years. He makes the following positive statement:—

> "I have brought nearly fifty people to her, after taking all ossible precautions to prevent her obtaining any inforation about these people. They were informed by Mrs. iper of intimate facts which she certainly could not know eforehand. Even detectives were employed to make sure this."

Now William James says:—

> "I am absolutely certain that Mrs. Piper during her trance ıows a knowledge of things of which it is impossible for r to have had any knowledge during the waking stage."

Frederick Myers said:—

> "Messages were given to me and certain circumances indicated, which it was impossible for Mrs. per to have known about. Certain facts enunciated were ppressed in the report as too intimate. Many of these cts could not have been found out even by a clever detective, ıd many other facts could only have been discovered by eans of an improbable expenditure of time and money."

Sir Oliver Lodge says:—

> "Much of the information furnished by Mrs. Piper has t been acquired by ordinary methods. The knowledge at she has of things and persons could not have been rived at by the ordinary channels of the senses."

James Hyslop arrived at the same conclusions after ree years of patient investigations.

Well, gentlemen, if men like Richard Hodgson, mes Hyslop, William James, Frederick Myers, and iver Lodge, affirm, after prolonged investigation, at the normal senses do not suffice to explain the plies and the revelations of Mrs. Piper, we are not titled, without incurring the reproach of unstifiable blindness, to throw their assertions into e waste-paper basket or to consider them on a iori grounds as lying or erroneous.

It is true that in Mrs. Piper's case an explanation s been given which I do not consider legitimate. ıe facts are undeniable. But instead of supposing, I have done, that it is the unconscious intelligence of Mrs. Piper which has obtained this knowledge by channels at present unknown to us, Oliver Lodge, R. Hodgson, and even Myers, have preferred to assume that a human personality—that of a dead person, a spirit—has undergone incarnation in Mrs. Piper, and speaks by her voice, writes by her hand, thinks by her thought. This is the spiritualistic theory, which I cannot accept, even though in this special case it seems to furnish a very convenient and satisfactory explanation.

I do not wish to discuss this here. It is only a hypothesis, a theory, whereas I am resolved to remain on firm ground and not to lose myself in the clouds. Hundreds of positive experiments teach us that Mrs. Piper knows things which neither her sight, her hearing, nor her power of touch could have taught her. I merely adduce this as an authenticated fact, without wishing to pursue the subject further; since the spiritualistic theory rests on a very shaky basis, as, indeed, do all other theories which have been put forward to account for cryptæsthesia.

Three Other Instances of Cryptæsthesia.

Thus, if there were only the case of Mrs. Piper, it would be sufficient to establish the fact of cryptæsthesia (or supernormal knowledge). But there are many others of old or recent date which cannot be doubted. I will only quote three, although I might give a hundred or more.

1. From a villa in the centre of France a botanist starts on a mountaineering excursion; he does not return that evening nor the next subsequent days. Search-parties are sent out, soldiers from a regiment in the neighbourhood explore all the adjacent valleys, but in vain. At the end of a fortnight, a somnambulist, questioned by Dr. Osty, indicates the exact spot, where in fact the body of the unfortunate botanist is found, at the bottom of a precipice.
2. Mr. Myers is visited by a distinguished Dutch physician, M. F. Van Eeden, living at Bussum. Every precaution is taken to ensure Mrs. Thompson's knowing nothing about him, but when in an hypnotic condition, she says that his name is Bussum and that he is a gardener at Eeden. Mr. Van Eeden had brought a piece of a garment belonging to a young man who had committed suicide without informing anyone. Mrs. Thompson gives his Christian name and adds that he had blood on his throat, which is in accordance with the manner of his death.
3. One evening, on July 31st, 1914, in a retired suburb of Paris, Count Ugo Baschier (gifted with remarkable powers of clairvoyance), suddenly remarks while in a spiritual trance: "A very important personage is about to be assassinated; what a quantity of blood. What time is it?" "It is 21.40 o'clock." "Well, something is happening near the Boulevard des Italiens." And, as a matter of fact, at 21.35 o'clock the great orator, Jaurès, was assassinated by an individual who had not divulged to a soul his intention of committing this infamous crime.

Are not these instances sufficient to justify the conviction that there are other ways of attaining knowledge than those through the ordinary senses?

In Apparently Normal Persons.

Further I will adduce other facts, possibly even more demonstrative, since they do not refer to persons in a state of trance or of hypnosis, but to others, still rarer and quite exceptional, who, when in an apparently normal condition, give evidence of second-sight, clairvoyance, cryptæsthesia.

Dr. Chowrin, superintendent of the asylum at Tambow, had under close observation over a prolonged period a woman, Mme. N., who was subject to grave nervous trouble. She could read letters that had been carefully sealed, and written so small that they could not be deciphered without a magnifying glass and enclosed in sensitive photographic paper. It was definitely ascertained on opening the envelope that it had not been tampered with. Before a medical commission Dr. Andreeff writes: "In the sands of Arabia there grew three palm trees, between which flowed a gurgling stream." Mme. N., taking the sealed letter, says: "A vast country, it is sand, three trees, very tall, I have never seen anything like it, a stream of which I can distinctly hear the murmur."

Mr. Resse, a Polish Jew, now in his eightieth year, a naturalised American, has given striking proof of cryptæsthesia before Edison, J. Maxwell, Schrenck-Notzing, Hereward

Carrington. Maxwell writes different questions on seven pieces of paper. Resse did not handle any of these papers, but gave exact replies to the seven questions. On one J. Maxwell had written: "What is my mother's name?" Resse replied: "Mary Angelina," an uncommon name of which he had certainly no previous knowledge. Schrenck-Notzing considers that Resse is one of the most extraordinary men of our time. On five pieces of paper Schrenck-Notzing had written different questions. Resse scarcely touched them and could not possibly read them, but he replied to each question. "What is my mother's name?" "When are we going to Germany?" "What is my eldest son's name?" &c., without any (normal) knowledge of the matter.

Prof. Schottelius at Stuttgart, Mr. Heymans at Groningen, Herr Tischener at Munich, Prof. Lombroso at Turin, all give analogous instances, equally striking.

In Paris Miss Briffaut, without entering into a trance or hypnotic condition, gave marvellous proofs of clairvoyance. My learned friend, the eminent physician, Arnaud de Gramont, pays her a visit under an assumed name. She tells him that his son was called S. . . . and that his name ended in *mont* (Sanche de Gramont), that he was an aviation officer, and that he had been killed, which was unfortunately true. Without disclosing her name, the Marchioness de Montebello goes to see Miss Briffaut, who says to her: "I see L. Louis (Madame de Montebello's son was called Louis). He was killed in the war, it is your son." "No," replied Mme. de Montebello. "All the same, he shows me that he had a sudden death." Now Mme. de Montebello's son had before the war been killed by lightning.

My daughter, Mme. de Ber, goes to see Miss Briffaut, who knows her name. Miss Briffaut speaks to her of my dear son A., an officer in the Flying Corps who was killed in the war, whom she may have known. But she repeated to my daughter an intimate conversation which she had with him two years before the fatal event, and which she had never divulged to anyone.

THE FACTS CANNOT BE DENIED.

Now, my dear Colleagues, these facts cannot be denied. To adopt the weighty words of Sir Oliver Lodge, "to deny them is to belittle oneself with the excuse that they are not in accordance with the principles of that commonplace classical science which we teach." Moreover, with Geley and other learned psychologists, I can myself bear witness to similar facts even still more astonishing and demonstrative if possible. I may quote the powers of a distinguished Polish engineer, Mr. Stephan Ossovietzki, who does not, however, care to make these experiments though he is invariably successful when he undertakes them. In bright light he takes the sealed and opaque envelope offered to him, feels it vigorously without looking at it, presses it, crumples it, and then declares its contents. Neither Geley nor I take our eyes off the envelope and we open it ourselves. We do not know the contents since it was addressed to me by Miss de Noailles, who is not present. Stephan, after taking the letter, says to me: "It is the inspiration of a French poet, perhaps Rostand; they are the verses of Chantecler, recited by the cock. I see the night and the light." Now Miss de Noailles had written: "C'est la nuit qu'il est beau de croire à la lumière. Edouard Rostand." These verses from Chantecler are said by the cock.

My illustrious friend, Sarah Bernhardt, sends a sealed letter to me in Warsaw, which I keep carefully from the moment the postman delivers it to me until I give it to Ossovietzki, who feels it, presses it in every direction, while Geley watches him assiduously, and says: "Life appears humble to us because it is . . . . (a word so French that I cannot read it—a word of eight letters)." Sarah Bernhardt had written: "Life appears beautiful to us because we know it to be ephemeral." I have made drawings which Stephan has reproduced faithfully. One paper he was able to read was enclosed in a leaden tube. Another time I wrote the word "thou" on a paper which I rub into a little ball in my hand. Ossovietzki reads "thou." No cheating had been possible. I am as certain of this as of my own existence, and in order to attest my faith I should not hesitate to condemn a man to death on the strength of it. When a jury condemns a man to death they have less certainty than I have of the genuineness of my experiments.

A NEW CHAPTER IN PHYSIOLOGY.

Gentlemen, I have now laid before you the facts and I venture to hope that your minds will no longe be open to doubt in spite of the novelty of my conclusions. You will agree with me that other mean are open to knowledge than those of the norma senses; that hypnotics, that mediums, or whateve they may be called, exist. We can sometime apprehend truths which neither sight, hearing, no touch can fathom. If I have been desirous o addressing you on these matters in this importan meeting, it is because I consider them to be an outcom of physiology. Yes, it is a chapter of physiology, new chapter which I want to introduce into our classi science. And I think too highly of the wisdom o physiologists to doubt their admission of what experiment has demonstrated. It would be as if they said "I no longer believe in the experimental method. have my theories, and the experiments that yo adduce, however elaborate, numerous, or methodica they may be, have no power to change them."

But you will not commit this sacrilege. You wil forget your theories and you will bow to facts. Fo the facts are there, in quantity, and inexorabl Claude Bernard, the master of us all, did not care fo theories; he established facts and he laughed a theorists who set up against him the vulgar, so-calle common classic opinion. In the same way, whe objection is taken to these exact experiments, to thes minute observations, as being opposed to the ordinar conception, to the opinion of Aristotle, of Locke, Descartes, of Claude Bernard himself, I have th right to smile.

I have often been told that courage was needed t sustain my opinions on cryptæsthesia. This is mistake. No courage is needed to defend truth. O the contrary, courage is needed—a bad courage—t deny the value of experimentation, to throw withou examination into the broad ditch of errors thi formidable weighty collection of undeniable fact more especially since this new physiology will no alter anything in the other physiology. It add something, it destroys nothing. The pneumogastri will continue to stop the heart, strychnine wi continue to produce convulsions, the respirator quotient will have the same number. The fact tha our intelligence perceives unknown vibrations do not modify in any way the laws of sensory perceptio Fechner's law still remains intact.

Perhaps it is not sufficiently understood that the are *contradictory* facts as well as *unusual* facts. Th access (to our subconscious intelligence) of thes mysterious vibrations is an unusual phenomeno but it is a phenomenon which is not in contradictio to anything. It is a new truth, that is all. And th new truth is wonderfully in agreement with th amazing notions which modern physics opens to u At this moment I cannot hear any concert in th hall, nor do you; you might even assert that the are no musical vibrations here. What a mistak If a wireless receiver were placed here, we should a immediately hear a concert that is taking pla perhaps three miles or even 100 miles away. Th receiver proves that the vibrations are present. Th it is with these mysterious paths of consciousness they do not reach us, but they are there. Only sensitive person, in other words, a receiver, is neede to prove their reality. Therefore do not hesitate accept this new fact that unknown vibrations stri an intelligence and bring to it unexpected knowledg

Here is a field spread out for your investigation It is true that the difficulties are great. But whe has difficulty turned us away from the study of an problem? On no account be put off by the credulit of the spiritualists. I do not wish to speak ill of th spiritualists, in spite of their having frequently bee hard upon me. But we do not share the sam principles. I believe only in science, experiment an observation. But they have ready-made theorie They start from the idea that there is a survival the soul and they endeavour to find in the facts confirmation of this conviction. I certainly do no eny that their theory deserves to be examined. In pite of puerilities and absurdities it subsists; although erribly fragile, it often gives a more satisfying xplanation than any other. All the same I cannot ake up my mind to accept it.

ATTITUDE TOWARDS FURTHER STUDY.

Before a theory is established the facts must be xamined. This shall be your task, my dear colleagues. should like to see physiologists of ripe experience ring their powers of careful inquiry to this attractive tudy of cryptæsthesia. They must first read the terature on this subject, and become acquainted ith the experimental methods which we have, among s, initiated, and perhaps invent others. And the arvest will be abundant. For if you have, as I am ssured, faith in science, do not remain shut up in he old structures where too often it is confined. arch boldly forwards. Do not fear light and air. ook around how all is transformed. Physiology as no right to remain a backward science, when her reat sister, physics, takes such a lofty flight. We ow know that there are vibrations everywhere, ven when we cannot directly apprehend them. herefore why not admit that certain vibrations xist which strike the intellect in order to bring to he brain knowledge through this?

Can physiologists and medical men assert that they ave completed the physiology of the brain? that here is nothing further to be discovered about it? nd that they have delimited all the modes of vibration of which it is capable? The brain is a much ore complicated machine than we are wont to onsider it in our innocence. Why may not this arvellous machine be sometimes capable of pereiving vibrations which pass unknown to consciousess? This, my dear colleagues, is physiology. Study his special sensibility of the brain. Give all your ind to this study. According to a formula which s dear to me: Be as bold in hypothesis as you are horough in experiment. At present we understand othing about the phenomenon of cryptæsthesia, and e shall very likely long remain in this condition. But, deed, have we really ever understood anything dequately? Is not everything a mystery, even in he case of phenomena which have been the most tudied and from the earliest times? How does ervous vibration cause the muscle to contract and hen to burn up the sugar? How does light acting n the retina provoke the phenomena—and strangest f all—the idea of light in a living consciousness? ow can two gases in combining give a substance hich is a liquid and yet their atoms continue unhanged? How is it that there are stars whose light akes 30 millions of years to reach us? We understand othing at all of this, yet all this is science. For science as not the pretension of understanding facts, but of stablishing conditions.

To you, my learned colleagues, to you, the young en who are listening to me and who perhaps feel ome confidence in an old man, who, in spite of his ge, is still in love with science, to you all it falls to etermine the laws of this new chapter in physiology. ave confidence in science and do not fear to consider he experimental method as the supreme guide. cience will travel much farther than our stunted cience of to-day. We have sometimes been tempted o think that the facts discovered by our contemporaries were final, and to assign a limit, not very far istant, and a future not very brilliant to our presentay science. Balances, telescopes, microscopes, therometers, galvanometers, always more delicate and ore precise, have been to some degree forming our ery near horizon. But here we may enter a new orld, scarcely explored, before which we stand mazed like a Hottentot before the Hertz waves, the asteur microbes, and Einstein's relativity. This ew world is the unknown, the future, it is hope itself.

I firmly believe that you are destined to penetrate nto some of these mysteries. It will be to the onour of physiology. And more than ever I believe hat great destinies await it.

A CLINICAL CONTRIBUTION TO THE ÆTIOLOGY OF ACTINOMYCOSIS.

BY W. TURNER WARWICK, M.B. CAMB.,
F.R.C.S. ENG.,
ASSISTANT SURGEON TO THE MIDDLESEX HOSPITAL, W.

THIS contribution is concerned primarily with the record of two cases of actinomycosis, but inasmuch as they are cases of more than usual interest from the ætiological standpoint, it has been thought worth while to include some account of the hypotheses that have been advanced as to the life-history of the infecting organism, the main arguments that have been adduced in support of each, and the stage of the argument at the present time.

Although granules had been noted as early as 1845 in pus from a case of spinal caries by von Langenbeck (recorded by Israel, 1878), and by Lebert in 1848, the first correct explanation of their nature (a central portion of mycelium with circumferential clubs) was given by Harz in 1876, who investigated the granules obtained by Bollinger from a case of the disease in cattle, and who proposed the name of *Actinomyces bovis* for this parasite. Some years previous to this (1868) Rivolta had also reported on the granules obtained from tumours of the jaw in cattle, though not so accurately as Harz; later on Rivolta claimed priority of discovery, and suggested the name of *Discomyces bovis* (1878). In 1878 Israel recorded the first case in man, and his later researches, and those of Ponfick and others, established the identity of human and bovine infection. Acland was the second observer to demonstrate the lesion of actinomycosis in man. In 1884 Nocard published a report of the first careful study made in France of a mycelial disease in animals. He also, four years later, showed for the first time in that country a case of human actinomycosis. His patient researches into the subject have led, in view of certain objections that can be made against other names, to the attachment by some authorities of the term "nocardia" to certain forms of mycelial disease. When an attempt was made to isolate the mycelium in artificial media, different investigators reported different organisms, and mycelial diseases now known to be quite distinct from actinomycosis were investigated.

The Work of Bostroem and of Wolff and Israel.

For the moment we will only consider the work of two earlier investigators, inasmuch as their results indicate the two conflicting hypotheses with regard to the life-history of the ray fungus, about which there is still controversy. (1) Bostroem isolated from several cases an aerobic streptothrix, easily grown even at air temperature. This, as a result of laborious investigations, he found to be more or less akin to the mycelial parasites which affect grasses, especially in marshy districts. He therefore advanced the theory that the normal habitat of the organism is inside the husks or sheaths of barley and other grasses, and is conveyed from such sources to the mouth, where it gives rise to the characteristic lesion. This theory attracted considerable attention and has become the traditional teaching of the lecture room and text-book. (2) Wolff and Israel reported an anaerobic streptothrix, difficult to cultivate, growing best at body temperature. An alternative hypothesis follows from the results of these careful investigations, which has recently been pushed to its logical conclusion by the work of Homer Wright. It is that the organism is an inhabitant of the mouth (especially in connexion with carious teeth) and of other parts of the alimentary tract, and that in the presence of certain factors, one of which appears to be the presence of a foreign body (even such as husks of barley or blades of grass), is able to invade the tissues.

Terminology.

The inquiry began, as we have seen, around the granules associated with the disease that Bollinger described, but the interest of investigators soon tended to centre round the mycelium. It has been found that when a branching mycelial structure alone without granules is considered, the field of investigation is very much widened. Thus widely divergent diseases have been proved to be due to mycelial organisms, the relation between which is at present a matter for conjecture. Moreover, these organisms have been described and classified from the independent standpoints of the pathologist and the botanist, with the result that the nomenclature in the literature is very confusing. For practical purposes it has been found convenient to limit the term actinomycosis from the clinical standpoint to include those lesions only which present themselves as chronic inflammatory conditions tending to form abscesses and sinuses, from which the typical granules can be obtained. This clinical limitation is open to the objection that the same description would apply to the lesion of madura foot, but in the absence of a definite laboratory grouping, it seems to be the only possible one for the present.

With this limitation in mind, it is only necessary to note the usage of the following terms, their multiplication being due to conflict between pathologist and botanist.

Actinomycosis (*Actinomyces bovis*), suggested by Harz and Bollinger, and used with the above limitation.

Discomycosis (*Discomyces bovis*), suggested by Rivolta, with the same limitation.

Nocardiasis (*Nocardia*) was employed by Toni and Trevisan for the whole group of mycelial diseases, and has been used by others for the non-granule-forming groups.

Streptothricosis (streptothrix) was put forward by Cohn as a generic term, and has been adopted in Cohn's sense by the London Pathological Society.

Coni-streptothrix was suggested by Pinoy as an alternative to streptothrix, a term employed previously by botanists for another organism.

The Granules.

Since the granule is of such importance in the diagnosis of this group, it is necessary to inquire into the structure and significance of the whole and of each of its constituent parts. Typical granules consist of a central matted mass of branching mycelium with radiating club-like structures peripherally. They are easily visible to the naked eye, are of an ovoid or round shape, sometimes yellow, sometimes white, and are usually described as "fish-roe" or sulphur granules. If a little pus suspected of containing granules is shaken up vigorously in a test-tube with distilled water, the granules will, if present, settle quickly to the bottom of the tube, where they may be examined with a hand lens. A molecule of cellular debris in pus may give the appearance of granules, but is not usually so round, and, moreover, it disintegrates fairly readily when shaken up with water, or may not settle so readily. A granule should always be crushed and stained before a diagnosis is made. If crushed between a slide and cover-slip, the structure may be seen with a hand lens to consist of a transparent central portion and a granular opaque periphery. The former contains the mycelium, the latter the clubs (if present), usually surrounded by pus cells. Before attempting to grow the organism, the granules are washed in relays of sterile distilled water.

Significance of the Granule.

The majority of recent researches tend to show that by far the most common organism associated with clinically typical actinomycosis is the anaerobic mycelium of Wolff and Israel. The relation of Bostroem's aerobic mycelium to clinical actinomycosis is not as yet determined. Homer Wright suggests that this observer may have been working with either a cultural or a secondary contamination. An organism closely allied to Israel's gives rise to a lesion which Poncet described as pseudo-actinomycosis. Here the clinical course is less severe and more amenable to treatment, while the granules are supposed to be larger and scantier and the mycelium thicker. This form is aerobic but grows best at body temperature.

Other observers have also isolated different organisms in a small number of cases. Colebrook notes two atypical strains, both giving rise to granules, and suggests the restriction of the term actinomycosis to those cases caused by Wolff and Israel's fungus, and the application of the term para-actinomycosis to the remainder of this granule-producing group. Foulerton has described several pathogenic organisms under the names of *Streptothrix hominis* 1, 2, 3, and 4. He does not lay much stress on the presence or absence of granules, to which the majority of observers attach much importance.

In addition to conditions such as the above, granules have been found in certain bacillary infections: (*a*) Lignière and Spitze described an organism which they called "the actino-bacillus." Griffiths says this bacillus gives rise to the majority of cases of actinomycosis in cattle, but Colebrook found only one case on record of human infection with this bacillus. Foulerton maintains that this organism is really a streptothrix. (*b*) Colebrook found a mobile Gram-negative bacillus causing granule formation in the contents of an abscess in connexion with a tuberculous kidney. This he considered a secondary infection of low pathogenic power.

Branching Mycelium.

This consists of slender threads which show irregular but true branching, and sometimes fragmentation of the protoplasm which gives a faint resemblance to strings of cocci. Such branching forms have been found in many isolated cases of unique pathological conditions, and may frequently be found living as saprophytes in the mouth and other situations. In the granules they occur as a thick felted mass with a general tendency to a radial arrangement, and are stained by Gram's method.

The demonstration of branching mycelium is necessary for the diagnosis of the actinomycosis group (due allowance being made for the tendency of the mycelium to break up), but the presence of this structure alone is not sufficient for the diagnosis in the absence of granules. It is not absolutely settled yet whether this distinction between granule-producing and non-granule producing streptothrices holds rigidly It is quite conceivable that a pathogenic streptothrix may, under certain conditions, form the aggregations of filaments that make up the granules, and under other circumstances fail to do so. Certainly if the organism lives in the mouth as a saprophyte, as the second hypothesis demands, granule formation must be in abeyance.

Certain streptothrices known to be usually saprophytic are frequently met with, the best known being found in the mouth—e.g., Goadby's *Streptothrix buccalis*. Mycelial forms can be demonstrated fairly frequently if smears be taken from the contents of the cavities of carious teeth. It is, however, by no means certain that even those organisms definitely regarded as saprophytes cannot, under certain conditions become pathogenic. Thus, according to Chalmers Goadby's *Streptothrix buccalis* is the same organism as that which Hesse recovered from a case of inguinal and spinal granule-containing abscesses, and to which he gave the name *Cladothrix liquefaciens*. The question then arises: If fragments of branching mycelium are found in any lesion of the mouth, or in any abscess or sinus in the neck, does this necessarily mean that we are dealing with a primary streptothrix infection? The answer is probably in the negative for the other possible explanations of such a lesion are: (*a*) An actinomycotic lesion: It may be that on examining smears from healing actinomycotic sinuses, branching mycelium will be found without granules, while if scrapings be taken from the wall of such a sinus, granules may be found either on lens examination or after histological section. (*b*) A secondary (saprophytic) streptothrix infection. This must be considered when some other specific lesion is present which will account for the onset of the clinical lesion, when no granules are found on scraping, and when the condition heals readily after proper surgical treatment of the original infection. When a leptothrix (non-branching mycelium) is found in association with lesions about the mouth, it is usually believed that this infection is secondary and saprophytic, and it must be remembered that some of the streptothrices of dental origin do not usually appear to be any more harmful than a leptothrix.

I have found mycelial forms in smears taken from a sinus of the cheek in connexion with an alveolar necrosis, and also from a sinus in the neck that had resulted from tuberculous glands. Moreover, scraping from the sinuses showed no granule formation, and surgical measures dealing with the necrosis in the one case, and the tuberculous glands in the other, resulted in cure. In these cases my investigations were limited, as attempts at culture yielded a heavy mixed infection, and no growth of mycelium was obtained. I cannot find any record of cultural observations from such cases in the literature of the subject.

In a research into the mycology of tumours, Leyton isolated streptothrices from many tumours. He did not claim that the streptothrix was the cause of the tumour, nor would many pathologists be found to support such a view. It follows, then, that the streptothrix is an addition to the tumour, perhaps of no great pathological moment. If this conclusion as to the saprophytic nature of organisms found in relation to neoplasms is admitted, it should not be difficult to accept it with regard to those found in sinuses and abscess cavities near places where such organisms are known to exist. Further, Homer Wright is apparently of the opinion that Bostroem, in his historic researches, must have worked either with contaminating cultural organisms, or else with secondary invaders of the lesion. On this second supposition one of the comparatively harmless secondary streptothrices may even be found in a lesion originally caused by actinomycosis.

The Clubs.

It is necessary to state that some confusion has arisen in the use of this term. Thus it has been applied to ball-like swellings that are found on the hyphæ and elsewhere in certain mycelia in culture, and to the peculiar crystalline substance that caps the granule found in the tissues. The former are supposed to be spores, and are not a characteristic of the anaerobic organism of Wolff and Israel. The latter result from the interaction of the mycelium and the tissue fluid, and are believed to be a protective mechanism of the mycelium. They have been obtained in cultures in special media by Homer Wright. These are the structures which are entitled to be called the "clubs" of an actinomycotic granule. They are a marked feature of bovine lesions, but are very poorly developed in actinomycosis in human beings. Homer Wright attaches considerable diagnostic importance to their presence. They are not, however, a constant feature, though they may be found in a high percentage if a careful examination is made. They have been found in other organisms (e.g., tubercle) after an injection of large quantities of bacilli into the tissues. They are, therefore, neither pathognomonic nor a necessary component of an actinomycotic lesion.

Cases.

The following are the cases I have to record :—

CASE 1.—Female, aged 38, quite well until 1919, when, following on dental extraction under a general anæsthetic, she began to suffer from violent fits of coughing. Three or four months afterwards she coughed up a tooth with a large quantity of fœtid material. After this her attacks of coughing became less violent, occurring chiefly in the morning and after moving from a recumbent position. Her sputum was nummular in form and somewhat fœtid, not of the type ordinarily associated with bronchiectasis. She attended the out-patient department of the Middlesex Hospital for some time, and was admitted to the wards because discomfort was increasing and night sweats were profuse.

Condition on Examination.—She presented a somewhat cachectic appearance, and slight clubbing of the fingers was present. The chest revealed dullness on percussion over a large, somewhat tender area at the left base before coughing, while after any attack of coughing which resulted in the expectoration of a considerable amount of sputum, areas of amphoric breathing and bronchophony were to be found.

Streptococci and diphtheroid bacilli were found in the sputum ; an autogenous vaccine was prepared, and a dose of 3 million organisms given. Following on this the temperature rose ; there was a great increase in the amount of sputum, which became more purulent and offensive, and as the pain in the chest increased, the vaccine was discontinued. The next day a fluctuating swelling was noticed between the eighth and ninth ribs in the mid-axillary line. A skiagram of the chest showed increased opacity at the root of the left lung, and over the lower lobe of the lung.

The swelling was incised, found to be a small pointing empyema, and drained. A large quantity of yellowish pus containing small yellow granules escaped. Examination of the granules revealed the presence of a branching streptothrix. All attempts to grow it both anaerobically and aerobically failed, so that a complete report cannot be given. After the administration of potassium iodide (about 60 gr. per diem), the sputum gradually reverted to the nummular form, the operation wound slowly closed, and was giving no trouble when the patient left hospital. The temperature gradually settled down to approximately normal, rising intermittently to 99°, and very occasionally to 100° F. The patient was sent to a convalescent home within six weeks, where her general condition improved considerably. There has been no recurrence of the empyema up to the present, the sinus is completely closed, and her condition seems stationary.

CASE 2.—A healthy vigorous male, aged 22, wishing to join the police force, presented himself in May, 1921, for preliminary medical examination. The left lower wisdom tooth was found to be carious ; all the remainder were then, and are now, quite perfect. This tooth had never caused him any pain, and no sign of disease apart from the caries was noted in the mouth or elsewhere. He was accepted subject to the removal of the tooth.

The extraction took place on August 3rd, 1921, and was followed by some considerable inflammation which gradually settled down. No further discomfort was experienced until November, when he complained of pain all over the left side of the face. Within a week swelling of the cheek was noted. He was admitted in this condition to the Middlesex Hospital, and was found to be suffering from an abscess in connexion with this part of the lower jaw. The abscess was incised and drained, and the pus from it yielded pneumococcus on cultural examination. Later examination by X rays revealed a very much thickened mandible with several small sequestra.

Sequestrectomy was performed in December, and granules were found in the granulation tissue removed ; branching mycelium was demonstrated in the granules. The administration of potassium iodide in large doses was commenced. Several operations have been performed since for the removal of small sequestra. On the last occasion cultural observations were made by Dr. A. N. Kingsbury, who found that the organism began to grow under anaerobic conditions at 37° C. but the culture soon died out.

The condition has made gradual improvement, and there are now two or three scars of healed sinuses in the cheek, while the active area is limited to one sinus leading down to bone, and surrounded by an area of indurated skin of a bluish colour. X rays do not reveal any further sequestrum formation, and the affected area seems to be progressively diminishing.

Clinical Manifestations of Actinomycosis.

The organism invades the tissues through an abrasion, most commonly in a mucous surface, more rarely the skin. The lesion is found generally in connexion with some part of the alimentary tract, usually the mouth or cæcum. Progress of the lesion is at first by local infiltration, and there is a tendency for this to follow fascial planes. Erosion of bones—e.g., the spine—often occurs. The neighbouring glands are involved only by direct spread from the original site. They may, however, be infected by the secondary pyogenic organisms along lymphatic channels. Later the spread occurs by the bloodstream.

The following varieties are usually described :—

Cervico-facial.—Invasion takes place from the mouth through an abrasion of the surface, through a tooth socket in connexion with dental decay, or via the tonsils or salivary ducts.

Thoracic.—This infection may be primary or secondary. Two routes are described in primary cases ; invasion through the œsophagus leading to mediastinal infection, or through the bronchi, leading to pulmonary infection. Secondary invasion may occur either by extension from the liver through the diaphragm, or by metastases through the pulmonary circulation. All these forms tend to spread to the surface of the chest.

Abdominal.—A cæcal infection is most common; it usually commences in appendicitis. An infection of the rectum is also met with, but much less frequently. Lesions of the stomach have been reported but are rare. From any of these sources metastatic abscesses may arise in the liver.

Skin.—Actinomycosis of the skin and subcutaneous tissues as distinct from streptothricosis is rare. Quervain gives several cases occurring in the recent war associated with sleeping on straw. Pringle's classical case of peri-anal actinomycosis seems to point to an infection from straw.

Genito-urinary.—The tubes and ovaries have been affected alone, the route of infection being uncertain. The kidney has been reported primarily affected in about eight cases, but few of these have been due to Woolf and Israel's organism.

Other Situations.—Actinomycosis of the brain and of other organs only accessible by the blood-stream has been recorded in cases where no surface lesion has been found, and infection must have been carried through the blood-stream from some point not ascertained.

I do not propose to attempt to record the clinical course of the various forms. Excellent clinical accounts have been given in France by Poncet, and in England by Kellock and by Cope, both the latter leaning towards the theory of Bostroem, as indeed do most clinicians. Kellock, however, in attempting to account for the various social and occupational conditions of the persons affected, states "that one is compelled to conclude either that the infection has been much more widely spread than was formerly supposed, or else that the organism that is its cause has, like other forms of life, undergone a process of evolution, and changed its locality and habits."

Evidence Favouring Bostroem's Theory.

Finally, the arguments brought forward by the supporters of the two schools can be considered. The arguments in favour of Bostroem's supposition have been ably marshalled by Mattson, and may be presented as follows:—

(1) *Evidence from Cases in Animals.*—After recording the observations of Conn on the preponderance of actinomycosis in the flora of sod-soil, Mattson cites Jensen's record of actinomycosis in endemic form in cattle, especially in marshy districts and in lands reclaimed from the sea. He also recalls the historic observations of Bostroem, who found the remains of grain or its sheath in several of his cases, and of Johne who, whenever he noted barley sticking in the tonsils of pigs, found them covered with a fungus similar to, if not identical with, the ray fungus.

(2) *Evidence of Cases in Man.*—It is usually stated that the disease is more common in those whose occupation entails the handling of hay or straw. Hummel collected 13 cases in German literature of infection associated with a foreign body, usually a piece of barley corn. Soltmann reports a case in a boy of 11, the sequel of swallowing an ear of barley. A thoracic abscess developed which on incision was found to contain an ear of barley and actinomycotic granules. Cope records a case in a boy of 10, who swallowed a blade of grass which lodged in the right tonsil. An actinomycotic abscess developed behind the angle of the jaw, and through the sinus resulting from it a piece of grass was eventually discharged. Mattson himself adds a case of cæcal actinomycosis; further examination of a previously removed appendix revealed a concretion round a grain of wheat, but he does not record the presence of infection in the appendix round the grain. To the above cases may be added those of Quervain and that of Pringle, both mentioned above.

The evidence here is merely circumstantial, and it may be equally well argued that if the organism is already present in the mouth, the damage done by bits of straw which are yielding enough to escape the efforts of the tongue to remove them, is yet sufficient to permit the invasion of the organisms present. Moreover, if chronic sinuses are present in the mouth, it can easily be imagined that bits of straw would tend to lodge in them in the case of herbivorous animals such as cattle.

Evidence Favouring the Theory of Wolff and Israel.

In support of the alternative theory are the following facts and arguments:—

(1) The organism of Wolff and Israel, which has been shown to be the commonest organism isolated from clinically typical cases of actinomycosis, is anaerobic and grows only at body heat. It is difficult, therefore, to understand the connexion between this streptothrix and those found on grasses. As noted above, Wright thinks that even the organisms that Bostroem isolated from the cases he reported were either cultural contaminations or secondary infections of the lesion.

(2) Branching streptothrices exist in the mouth, especially in connexion with decayed teeth, and similar organisms have been found throughout the alimentary canal, least frequently in the acid-secreting stomach. The more easily grown aerobic forms have been isolated and described. It must be remembered, however, that the floral conditions existing in dental cavities and elsewhere throughout the alimentary tract render these situations unpromising sources from which to grow such a delicate organism as the actinomyces of Wolff and Israel.

(3) Lord injected the contents of teeth and tonsil crypts into guinea-pigs, and obtained club-shaped structures round branching mycelium. The objection to the conclusiveness of this experiment is that he did not isolate the organism from the material injected or from the resulting lesion in the guinea-pig.

(4) Clinical evidence of the dental origin of the lesion is not lacking: (*a*) A case recorded by Cope is of interest: The patient contracted actinomycosis as a result of an injury to his knuckles, sustained while knocking out an opponent's tooth; the opponent apparently had no actinomycotic focus. A similar case is recorded in America by McWilliams. (*b*) Cope also records a large central abscess expanding the lower jaw in direct connexion with the socket of a carious stump. The second case reported above, where the lesion followed the extraction of a carious tooth, is also significant. (*c*) Stengel records a case in which actinomycosis followed injury to the cheek by an instrument used in extracting a tooth. (*d*) The case of thoracic actinomycosis (Case 1) reported above also provides equally good circumstantial evidence. A case of thoracic actinomycosis is reported by Israel, in which he found the remains of a tooth in the bronchus. I believe other similar cases have been published, but I have been unable to trace them in the literature.

The main argument advanced by Mattson against this second theory is that actinomycosis never follows on surgical interference in the abdomen or mouth. This argument cannot be accepted lightly; Mattson himself records a case, previously mentioned, in which actinomycosis followed appendicectomy, performed apparently for acute appendicitis, and such cases are not uncommon. It is not often that actinomycosis is suspected at the time of operation for an acute attack of appendicitis. That diagnosis is prompted by the subsequent history. It is quite conceivable that the appendicectomy itself may have been the final cause determining the onset of actinomycosis in a certain number of cases of this type, and the course of events may then be compared to that shown in Case 2 recorded above. In this case it would be difficult to convince oneself that the extraction did not determine the onset of failure of resistance of the tissues.

When the onset has been less sudden and operation is delayed the disease may be found at operation to be definite and established. The course of such cases may be compared to that quoted above (recorded by Cope) of a central abscess of the jaw. It may also be noted here that cases of accidental infection from the gut by *Streptothrix eppingeri* following operative interference are reported by MacCullum and Foulerton;

Factors Determining Invasion.

It has been found by investigators to be very difficult to transmit the lesion of actinomycosis to animals. The general belief is that certain conditions must be present to enable the parasite to gain a hold in the new surroundings. These include such factors as the presence of a foreign body—e.g., straw in the fauces, or of other organisms. The well-recognised onset of actinomycosis after an acute attack of appendicitis is a clinical illustration of the effect of the latter, but a more definite relationship to certain bacteria is also proved by the discovery of bacillary organisms embodied in the granule of which they form the felt. Thus Wolff and Israel described Gram-positive micrococci; Klinger, the presence of Gram-negative cocco-bacilli, *B. actinomyces comitans* (confirmed by Colebrook). Inoculations from pure culture are not successful in producing progressive lesions in small animals, and recent experiments in the direction of determining the necessary combinations of mixed infections have given rather negative results so far.

In conclusion, it appears that most of the direct evidence supports the theory so strongly advocated by Homer Wright. Clinical evidence can at best only be regarded as circumstantial and may be used in support of either theory. The final solution of the problem, therefore, must be sought in the laboratory by cultural and inoculation investigations.

I am indebted to Dr. W. Essex Wynter for permission to publish Case 1, and to the late Mr. T. H. Kellock for permission to publish Case 2.

NOTES ON A LIMITED OUTBREAK OF ACUTE GOITRE IN A CHILDREN'S HOME.

By E. W. ADAMS, O.B.E., M.D. Lond.,
MEDICAL OFFICER, MINISTRY OF HEALTH;
AND
H. N. CROSSLEY, M.B., Ch.B. Manch., D.P.H.,
MEDICAL OFFICER, CHILDREN'S COTTAGE HOMES, BIRCH HILL POOR-LAW INSTITUTION.

In this paper we propose briefly to summarise the salient characteristics of a curious outbreak of acute goitre which ran its course during the earlier months of this year and was limited in incidence to one cottage out of a colony of nine occupied dwellings which constitute with one other cottage, unoccupied at the time, the Children's Cottage Homes in connexion with the Birch Hill Poor-law Institution. These Homes are situate near the village of Wardle and are about four miles distant from Rochdale. Epidemics of acute goitre of greater or less extent have been previously described (McCarrison, Guillaume, Simon, &c.), but appear to be of sufficient rarity still to merit record. Moreover, the causation of such epidemics is, as yet, obscure, and though in the present instance it has only been possible to arrive at certain tentative conclusions, we think that an account of the clinical features of the epidemic ought to be placed on record both in the hope of eliciting the experience of others who may have encountered similar outbreaks and of assisting future observers.

Though the chronic form of goitre seems to be rife among the children of all the cottages (ages 3–15 and of both sexes), the sole brunt of the acute epidemic was borne by cottage No. 3. The inmates of this cottage at the date of the epidemic numbered eight—boys of ages between 4 and 10 years, and all these children were affected. The adult staff of this cottage, consisting of a foster-mother and her husband (resident) and a female cleaner (non-resident) escaped.

There is, unfortunately, no record of the previous thyroid state of these boys, though it is known that one of them, on admission to the cottage some months before, had been observed to possess a distinctly visible thyroid, and it is probable, judging from the results of an examination of the children in the remaining cottages, that another case or two of slight chronic enlargement might have been detected had there been occasion especially to look for it before the commencement of the acute outbreak. However this may be, the course of events is sufficiently striking, as is evidenced by the fact that no other cottage of this colony has, during the period of tenure of the present medical officer (H. N. C.), ever experienced the dramatic thyroid flare-up which was the lot of cottage No. 3.

Outbreak of the Epidemic.

The course and clinical symptoms of the epidemic were as follows: On Jan. 7th, 1923, the boys of No. 3 cottage were inspected during the course of the ordinary routine examination by the medical officer (H. N. C.). Though the examination was not specially directed to any one region, nothing in the appearance of the boys served to draw attention to their thyroids, and no enlargements were noticed save in the case of the boy above mentioned. On Jan. 10th, S. U., aged 9, the boy who had already been noted as slightly goitrous, was seen by the foster-mother to have a very marked goitrous swelling far in excess of the boy's normal fullness in the region of the throat. On the 12th two other boys, T. A., aged 9, and L. G., aged 8, were also noticed to have large thyroid swellings. On the 13th all the remaining five boys presented thyroid swellings, distinct in all, though varying in degree individually. In all the cases the swelling was soft, elastic, painless, and non-inflammatory. The right lobe was invariably more affected than the left, and there were no glandular enlargements elsewhere. In some of the cases there were carotid thrills and enlarged venules over the gland and upper sternum which disappeared later. In no case, however, was there any thrill over the gland itself, nor were any of the signs of hyperthyroidism present. The thrills and congested venules noted were, therefore, probably merely mechanical effects. The pulse was variable, but allowing for age and the psychological effects of the examinations the rate of the pulse seemed in no case to have any special significance. The temperature was normal and remained so always. The general health of the boys was unimpaired. The picture was that of a symptomless acute enlargement of the thyroid gland.

Systematic physical examination of the boys revealed nothing further, save that carious teeth were present in two of them, and some faucial congestion was noticed in five of the eight boys. The bacteriological reports on these throats were negative as regards diphtheria and diphtheroid bacilli, but gave the predominating organisms as streptococci. The lad S. U. (the first case noticed) is a mental deficient. The youngest boy (aged 4) is a sickly-looking lad, but has no definite disease.

Course of the Epidemic.

Such, then, was the state of affairs at the commencement. The further course of the epidemic will now briefly be summarised. The maximum thyroid enlargement appeared to be rapidly attained in a few days, and after a period varying between five to seven days, the thyroids began to subside, so that by the seventh day appreciable diminution was noticeable in all the cases. This subsidence continued, though not without fluctuations, for about a fortnight, after which a stationary period occurred, during which it was difficult to detect, either by measurement or otherwise, any appreciable change. By Feb. 1st, however, one of the cases, at least, was considered to have returned to normal. After this date progress, though slow, was more readily appreciable, and by March 6th the thyroids in three of the boys would not have attracted attention, while in four of the others the thyroid enlargements could only have been described as "slight." In only one boy of the eight would the condition of the thyroid at once have arrested the attention of an observer at the first glance. During the period Feb. 1st to March 6th a diminution of as much as 2 inches in the neck circumference was observed in the boy S. U., while in another boy a subsidence of 1 inch was recorded. The remaining cases showed decreases varying from half to three-quarters of an inch.

Slow but sure progress continued to be made, and by April 8th there was room for difference of opinion as to whether the thyroids could now be considered to be enlarged in five of the boys; in two the goitre was classified as slight, and the boy S. U. showed a further diminution in neck circumference of half an inch (making 2½ inches in all since Feb. 1st). His was the only case at that date where the enlargement was at all obvious, but it was considered probable by the observer (H. N. C.), who was in a position to compare his state before and after the epidemic, that he had returned to his former condition. The last joint examination of the cases was made by us on May 22nd. The condition as regards the thyroid swellings, save in the case of S. U., was not appreciably different from that described on April 8th—that is to say, in two of the boys there was still slight goitre and in five the thyroids might be described as normal.

We think that the thyroid state of the inmates of No. 3 cottage does not now materially differ from that existing in many of the other cottages where no acute epidemic has occurred, and where a similar proportion of cases of slight goitre has been detected. We therefore suppose ourselves justified in assuming that the acute epidemic in this cottage may be considered to have come to an end, and that the residuum may be regarded as the state which would probably have been found had attention been specially directed to the thyroids in the children of this cottage prior to the occurrence of the epidemic.

As regards the boy S. U., the thyroid was slightly larger than at the examination on April 8th. These fluctuations in chronic goitre are not uncommon. (The goitre in this boy, however, subsequently rapidly returned to the condition described on April 8th, and has remained in that state up to date —August 16th. No change in respect of the other children has occurred since the last note.—H. N. C.)

Ætiology.

As we have no desire unduly to prolong this paper, which is written mainly with the object of putting on record the physical characteristics and clinical course of the epidemic, the results of some rather laborious inquiry to ascertain the cause of the outbreak will only be stated baldly and briefly. This is the easier done since, unfortunately, the results of such inquiry are mainly negative.

There is nothing notable in the previous health of the boys of this cottage, except that there had been a slight epidemic of measles among them which occurred in the early part of December, 1922. Three of the boys suffered, but all had completely recovered by the date of the goitrous outbreak. There had been no cases of mumps, scarlet fever, diphtheria, or other infection on tracing the records back for several months. The faucial congestion found in five of the boys at the early examinations has already been noted. Besides what may be termed the permanent population of this cottage, a certain number of children pass through it on probation before allotment to other cottages, thus constituting a sort of floating population. Two children so passed through near the date of the epidemic—viz., a girl, E. L., aged 13, and her brother J. L., aged 10, who were admitted on Dec. 30th, 1922, and stayed seven days, leaving on Jan. 6th—i.e., four days before the first case of acute goitre was detected. E. L. was found to have a slight goitre, which, however, had been present some time and was probably due to physiological causes. J. L. was goitre-free. The adult staff were found healthy, the only illness recorded recently being a slight attack of influenza, from which both the foster-mother and her husband suffered. Among the inmates of the other cottages, recent illnesses included one case of measles in each of two cottages, one case of scarlet fever which was promptly sent away and gave rise to no further cases, and some trivial and ephemeral complaints of no import. The children of the various cottages come into contact at play, on the way to school, and so on.

As regards the immediate neighbourhood, goitre is endemic in the district, according to the view of Dr. D. McGill (medical officer of health, Wardle), but there is no consensus of opinion that the goitre incidence is really higher in any part of Lancashire than in most other districts. Inquiries made in the schools of the area showed, however, that goitre, usually of a slight or moderate degree, was not uncommon among the children. In these inquiries we received very valuable assistance from Dr. J. J. Butterworth (M.O.H. and School M.O., Lancs County Council, &c.) and from Dr. W. M. Ash (Assistant County M.O., Lancs, and School Med. Insp., Lancs), who examined the thyroid states of 249 school children attending schools in the neighbourhood and compared the results with those found in 83 of the cottage children who comprise the population of the cottages other than cottage No. 3. Dr. Ash's figures show 33 cases of thyroid enlargement of varying degree among the 83 cottage children as compared with a total of 30 cases among the 249 school children. These are significant figures, and at least show that there is some abnormality in what we may call the thyroid soil of the cottage children generally. It is of some interest to compare these figures with those obtained by Dr. C. N. Atlee in an investigation into the prevalence of goitre among children under 12 years of age in the South-Eastern quarter of London. Seventy-seven cases were found among the 1839 children examined.[1] No other cases of acute goitre were, however, encountered, with one doubtful exception.

As regards other illnesses, measles seems to have been the only prevalent affection recently among the children of the surrounding neighbourhoods. The state of affairs, therefore, seems to be that though there is a case for inquiry whether goitre is or is not unduly prevalent in the area around Rochdale, there is no doubt that a high degree of thyroid instability is present among the children of these Homes generally, and that some special factor (or combination of factors) has acted as a detonator to explode this unstable material in cottage No. 3.

We feel justified in saying little more than this at present. Neither the general cause of the endocrine instability nor the special factor which produced the explosion in a particular cottage emerges at all clearly. On the general point it may be said that the cottage buildings, though sound and comfortable, are not, perhaps planned to give the maximum amount of light and ventilation, and it is possible that experience may show that some revision of the diet and régime may be advantageous. But chemical and bacteriological examinations of the water and milk have so far afforded no real clues, nor have other inquiries which cannot be detailed here.

We are just as much in the dark as to the nature of the spark which ignited the material in one special cottage. So far as possible all the contacts of the cases have been traced and examined, but no definite results emerge. The conditions of life in all the cottages are the same. The water-supply and milk-supply are the same for all. The dietary is the same; the food is obtained from the same sources of supply. The sewage disposal is on one plan. The cubic space and floor space per boy in the No. 3 dormitories do not materially differ from those for the children in the other cottages. Careful measurements have been made in all these respects and these are the general results. The inmates of the affected cottage appear to get as much light, air, and exercise as the inhabitants of the other cottages, and the past general health of the boys of this cottage appears to have been at least equal to that of the children of the remaining ones, with the exception of the measles epidemic. But though only three of the eight children in cottage No. 3 had measles, this fact, coupled with the condition of the fauces in the majority, may have some significance, and may possibly mean that the special factor must be looked for in some form of infection. This appears to be all that can usefully be said at the present moment in the matter of the ætiology, though we are not without hope that some more definite statement may be possible at a future date as the result of continued observations.

THE CAUSES OF HEADACHE.*

BY A. B. PAVEY-SMITH, *M.C.*, M.B. CAMB.,
F.R.C.S. ENG.,
AURAL SURGEON, ROYAL BATH HOSPITAL, HARROGATE.

HEADACHE may be associated with almost any form of illness; it may be so trivial and so persistent as in time to be regarded almost as normal; it may be so severe as to make life nearly intolerable; and there is hardly a symptom so common and at the same time so little understood. It presents no outward and visible signs. Our knowledge of its character must depend almost entirely on the patient's statements, and in a large number of cases we can only conjecture what is the actual process which causes the pain. But without some such conjecture, without some sort of mental picture of the origin of the symptom, its treatment can be little more than empirical and haphazard.

The classification of headache in most works of reference is, to my mind, entirely unsatisfactory. It consists in most cases of a partially classified list of conditions with which headache is associated, and nothing more. It gives no hint of how the headache is caused. For instance, "headache due to toxic causes" may be a useful pigeon-hole, but it conveys no very clear idea. I suggest a different classification, dividing headache into three main groups, as follows: 1. *Intracranial,* due to actual processes occurring within the cranial cavity. 2. *Cranial,* due to processes affecting the cranial walls and the air spaces contained within them. 3. *Extracranial,* due to processes affecting structures outside the cranial walls. By "process" is meant the actual organic condition directly responsible for the head-pain. Thus, in an intracranial headache (Group 1) the pain arises as a result of some intracranial change. This intracranial change may itself be due to some extracranial and more general condition, but the headache is only "extracranial" if the actual pain-causing lesion is outside the skull. These groups, in fact, refer to the starting-point of the pain, and not to the condition with which that pain is associated.

Intracranial Headache.

The intracranial group has two main subdivisions: (*a*) cortical, and (*b*) dural.

(*a*) *Cortical.*—This subdivision includes all headaches arising in the cortex. Almost all these may be classed as purely functional. They are due to exaggerated activity of that part of the cortex concerned with the sensation of the headache area. This form of headache may be the product of a perverted mental process without any organic lesion, and is usually associated with other symptoms of a hysterical nature. True migraine is also probably of cortical origin, the exciting cause being unilateral. Headache due to organic changes in the cortex *and arising* in the cortex must be rare. The cortex itself is quite insensitive, and the only organic process capable of producing a cortical headache must be one which stimulates exclusively the pain-perception cells connected to the painful area.

(*b*) *Dural.*—This subdivision probably accounts for he majority of headaches. Headache of this class is due to irritation of the nerve-endings in the dura mater. The cortex and cerebral tissues themselves have frequently been demonstrated to be quite insensitive; he inner lining of the skull, on the other hand, is well upplied by branches of the trigeminal and other ranial nerves, and in certain areas pacinian corpuscles are present. Moreover, the dura is homologous to periosteum, which is known to be pain-sensitive. The headache originates in the dura, the nerve-endings of which are irritated by pressure or inflammation. Anything which raises the intracranial pressure may hus produce a headache: (1) Cerebral hyperæmia and erebral œdema account for such headache as accompanies acute fevers, asphyxia, renal disease, toxæmias whether bacterial or otherwise, and many head injuries; (2) increase of cerebro-spinal fluid; (3) mass increase of cranial contents, by tumour, abscess, gumma, extravasated blood, &c. Any of these may produce pain by pressure on the dura in the absence of any inflammatory irritation of it. In a similar way, headache may result from inflammation of the dura acting alone, whether localised or general, acute or chronic. But the dural nerves appear to be far more susceptible to pressure than to inflammation. The intense headache of cerebro-spinal fever is immediately relieved by lumbar puncture, though in many cases the dura remains all the time in an acutely inflamed state. Headache of this type may arise in other conditions where these two factors, pressure and inflammation, are combined—whenever, in fact, pachymeningitis carries with it a high intracranial pressure. The importance of raised intracranial pressure as a cause of headache has been proved frequently. The severe headache of pituitary tumour is relieved by decompression, that of meningitis by lumbar puncture. Reports on head injuries during the war showed headache to be more severe in, and more particularly associated with, those cases in which the skull was intact, while cases of much more extensive trauma with exposure of the cranial contents were relatively free from headache.

Little is known about the regulation of intracranial pressure, as regards either blood-supply or production and absorption of cerebro-spinal fluid. It is reasonable to suppose that headache associated with a high systemic blood pressure, such as that of chronic nephritis, may be relieved as a result of lowering the blood pressure. At the same time it is quite as possible that the cerebral congestion is due to the action of toxins of intestinal or other origin, and that depletion cures the headache by removal of the toxin. Headaches of this type—high-pressure headaches, in which there is no intracranial inflammation—tend to be dull, and are increased on lying down; they are relieved by anything which lowers the pressure; if intermittent they do not tend to recur constantly in the same place; they are not accurately localised.

I think it possible that in the great majority of cases in which headache occurs as one of several symptoms, as part of a recognised syndrome, or as one feature great or small in some general condition, the headache is of this type—that is to say, it is due to irritation of the dural nerve-endings from increase of intracranial pressure, general or partial, transient or progressive. The headache which occasionally follows lumbar puncture appears after this a paradox; but, unlike most forms, it is relieved by lying down and made worse on sitting up. It is almost certainly due to pressure of the brain on the tentorium and basal dura owing to lack of the supporting fluid cushion. One form of headache met with in anæmia resembles this; it is possibly due to a diminished secretion of cerebro-spinal fluid.

It will be obvious in the light of clinical experience that the pressure explanation of headache is inadequate. There are unknown factors which determine the relation between the severity of the headache and the degree and direction of the pressure. Time is one of these factors. An increase of cranial contents arising slowly, as in cerebral tumour, may reach a higher level before headache is produced, as the tissues have time to adapt themselves. In the case of the rapid increase from active or passive congestion headache is likely to arise sooner, the inelastic walls of the cerebro-spinal system having had no time to stretch. It is also probable that some areas of dura are more sensitive to pressure than others.

Cranial Headaches.

The cranial group includes headaches due to disease of the cranial walls, and may be classified in two main subdivisions: (*a*) disease of the cranial bones, and (*b*) affections of the nasal sinuses.

(*a*) Chronic osteitis of the skull, such as occurs in the common extensions of middle-ear suppuration, is not often associated with headache. Indeed, in chronic otitis media, headache, other than the frontal "intracranial" type which may be associated with any septic absorption, should be regarded as a danger signal. It is almost always due to the disease reaching the dura with the production of an extradural abscess. Such a headache is not usually very severe; it tends to continue, showing little variation, and is fixed to a definite place, over which there is usually tenderness to deep pressure and percussion.

---

* A paper read before the Harrogate Medical Society.

(*b*) The nasal sinuses are a much more prolific source of headache; the very intimate relations of the frontal, ethmoid, and sphenoid sinuses to the interior of the skull, and the fact that all these cavities are in communication with the nasal passages, are open to the same infections, and are lined by a sensitive mucous membrane, make it surprising that headache is not more universal. Headache arising from a nasal sinus is due, in almost all cases, to inflammation of the lining and pressure. The latter is, again, as in "intracranial" headache, the important factor. It is *retention* of secretion which causes the pain. For this reason the headache bears no direct relation to the severity of the infection or inflammatory process. A mild catarrhal sinusitis producing clear mucus may cause a severe headache, while a profusely suppurating sinusitis with destruction of the mucous lining may be painless. The determining factor is the efficiency of the outlet. This applies to *chronic* sinusitis; it is probable that no acute sinusitis is painless.

The openings of the nasal sinuses are small. This fact accounts for the relative infrequency with which infections of the nose reach the sinuses; but, at the same time, it has the result that a small amount of swelling is sufficient to close the opening and cause retention. Several of these ostia, again, are situated in a part of the nose so narrow that a very slight degree of deformity will prevent efficient ventilation and favour an inflammatory process around the opening, which is already at a disadvantage. This is particularly the case with the frontal sinus, of which the narrow tubular opening lies under cover of the middle turbinate. If the latter is swollen, hypertrophied, or pressed outwards by a deviated septum, the opening may become closed. Such a closure may cause headache without any true infective sinusitis. The air in the sinus becomes absorbed and a partial vacuum results. This gives rise to congestion of the lining with frontal headache and tenderness; the condition has been described by Sluder as "vacuum frontal headache." A headache of this type is supraorbital, usually unilateral, worse in the morning, and increased by close work with the eyes; the last symptom is due to the pull of the superior oblique muscle on the trochlea which is attached to the thinnest part of the floor of the tender sinus. The ethmoid and sphenoid sinuses communicate with the nasal cavities through comparatively simple though small orifices, and not by a tubular or grooved opening like that of the frontal sinus. This simpler type of opening, from its smallness, can easily become blocked by inflammatory swelling of its edges, but is not affected by lateral pressure, such as results from nasal deformities and causes closure of the frontal sinus. The latter is susceptible to both forms of attack, and this is one of the important factors which make a frontal headache the commonest clinical variety.

Nasal sinus headache has certain characteristics. It is frequently the only symptom, the patient being otherwise in good health. In acute sinusitis it may be neuralgic in character or intense and throbbing. In more chronic cases it may take any form, including that of a sense of uncomfortable pressure from without. It tends to be localised to one area, and, if recurrent, the same area is affected each time. Anything which increases the congestion of the lining immediately increases the headache. Thus the patient may have discovered by experience that stooping to pick anything up is accompanied by the most acute pain. The same applies to coughing, and, to a certain extent, to jarring movements. Periodicity is a very marked feature. The pain is usually worse in the morning. In connexion with this fact it must be remembered that the frontal and sphenoidal sinuses drain by gravity in the erect position only, and consequently tend to fill up during the night. This morning pain is so definite and punctual a feature that it has been called "sun-pain," from a mistaken idea that the heat of the sun was the cause; cases have actually been diagnosed as malaria from the regular recurrence of the headache. There is a general tendency for the pain to come on suddenly, to reach its maximum rapidly, and, after a variable period, to vanish with equal suddenness.

As regards position, a sinus headache is usually unilateral—the opposite to "intracranial" headache. In the case of the frontal sinus it is referred to the supraorbital region, and is associated with local tenderness, especially of the floor under the inner third of the supraorbital margin. With the deeper sinuses, ethmoidal and sphenoidal, localisation is by no means so definite. Sphenoidal pain is referred to the temporal regions, the occiput, or the vertex. In the last position the "heavy weight" sensation is not uncommon; a fact which must be remembered before a diagnosis of *clavus hystericus* is made. Pain arising in the ethmoid may be referred to the back of the eye or the region of the inner canthus. Some of these features occur, of course, in headaches of intracranial origin. They are not in themselves definite evidence of sinus mischief; nor are they by any means essential to a case of sinusitis.

The following points, in a case of headache, should arouse a suspicion of the pain being due to sinusitis:—(1) If the headache is unilateral, and especially frontal; if it shows a marked periodicity; is worse in the morning; has a sudden onset; always recurs in the same place; and is immediately greatly increased on stooping, then a sinus should be suspected. (2) If, in addition, there is a history of "catarrh"; if the nasal airway is defective on either side (and patients may be quite unaware of this); and if the patient is otherwise in good health, sinusitis is still more likely. (3) Finally, if the headache is relieved by inhalations of steam, medicated or not, it can be definitely concluded that its source is in the nose.

There is, in addition, a type of headache due to what I should like to call the "excitable nasal sinus." Such a sinus is one which, under ordinary conditions, gives rise to no trouble, but which, owing to structural variations or to a slumbering sinusitis, "flares up," as it were, on the slightest pretext. Many cases of menstrual headache which are frontal and unilateral are undoubtedly of this type. The same condition is also probably at the bottom of many similar headaches which come on with fatigue, constipation, toxæmia, and other systemic conditions.

Extracranial Headache.

The third main group, the extracranial, includes those cases in which, as I imagine it, during the course of the headache the cranial contents and cranial walls are in a perfectly normal condition. The following types of "extracranial" headache may be briefly considered:—

Ocular Type.—These headaches are due to fatigue of intra- and extra-ocular muscles, generally from errors of refraction; from increased intra-ocular tension, inflammation, and other causes. They are usually worse in the evenings, the opposite to nasal headache. The pain is referred along branches of the trigeminal nerve, usually to the frontal and temporal regions; but it may be occipital.

Dental Type.—These are referred headaches of dental origin. In the majority of cases referred dental pain, as distinct from actual toothache, is found over face areas, but the upper incisors may give rise to frontal headache.

Nasal Type.—Pressure of the middle turbinate against the septum has been advanced as a cause of homolateral frontal headache, but it is common to find the middle turbinate in close contact with the septum, and a total absence of headache. I think it much more probable, in the light of Sluder's work on the vacuum frontal sinus headache, that the pressure of the turbinate against the septum is not the important factor in producing the pain, but that such a state of things is keeping up one of the forms of frontal sinusitis.

Ganglionic Type.—The sphenopalatine ganglion (Meckel's ganglion) lies, covered only by the nasal mucous membrane and a little areolar tissue, just behind the middle turbinate. It has intimate connexions with the fifth and seventh cranial nerves and the sympathetic, is more superficial than any other ganglion in the body, and is exposed to nasal infections. If this ganglion become inflamed it gives rise to the sphenopalatine syndrome, one symptom of which is headache of the very characteristic type described by Sluder as follows :—

> "A coryza of variable severity, followed in a short time by pain at the root of the nose, in and about the eye, upper jaw and teeth, extending back to the temple, about the zygoma to the ear, causing earache, emphasised at the mastoid, but always severest at a point 5 cm. behind this ; thence back to the occiput and neck ; it may extend to the scapula and shoulder, and in severe attacks to the arm, forearm, hand, and even finger-tips."

Half a minim of saturated cocaine solution applied over the ganglion stops all the symptoms immediately.

The Author's Schema.

Every headache, then, falls into one of these three main groups, and I suggest that this classification may lead to a clearer comprehension of the symptom.

1. *Intracranial.*

A. CORTICAL.—*Headache arising in the sensory cortex.*

(1) *Functional*—e.g., hysteria; neurasthenia ; migraine (hemicrania).

? (2) *Organic.*—? Disseminated sclerosis.

B. DURAL.—*Headache due to irritation of nerves of dura mater.*

(1) *Intracranial Pressure*—

(*a*) *Raised* by :—

(i.) Hyperæmia.

(α) Active—e.g., head injury ; fevers: nephritis ; bacterial toxæmias ; fatigue ; reaction after syncope ; meningitis ; constipation ; menstrual and uterine poisons (lead, alcohol, &c.), anæmia.

(β) Passive—e.g., asphyxia ; morbus cordis.

(ii.) Cerebral Œdema.—Head injury ; sunstroke.

(iii.) Increase of Cer.-spin. Fluid.—Hydrocephalus ; meningitis ; head injury.

(iv.) Increase of Cranial Contents.—Tumour ; cyst ; gumma ; abscess ; extravasated blood.

(*b*) *Lowered* by deficiency of C.-S. fluid ; *headache due to pressure of unsupported brain on basal dura and tentorium.*

(i.) Leakage.—Lumbar puncture.

(ii.) Hyposecretion.—Anæmia.

(2) *Inflammation.*—Pachymeningitis—localised suppurative meningitis ; subdural abscess ; G.P.I.

2. *Cranial.*

A. BONE DISEASE.—*Headache due to irritation of periosteal or dural nerves.*

Osteitis.
Periostitis.
Extradural Abscess. } —e.g., infected fractures ; extensions of otitis media ; syphilitic necrosis.

B. NASAL SINUSES.—*Headache due to irritation of nerves in mucosa lining.*

Sinusitis and Retention.—Headache without other symptoms or with nasal catarrh or obstruction.

"*Excitable*" *Sinus.*—Constipation ; toxæmias ; menstrual.

N.B.—Pain arising in the middle ear and mastoid is not ncluded under "headache."

3. *Extracranial.*

Headache due to irritation of nerves or nerve-endings outside the cranial wall, and referred.

(1) *Ocular.*—Muscular fatigue—Errors of refraction.
Hypertension—Glaucoma.
Inflammatory—Iritis.

(2) *Dental.*—Fronto-nasal headache referred from upper incisors—Dental caries.

(3) *Nasal.*—Pressure on septum—Headache with nasal obstruction.
Meckel's ganglion inflammation—"Sphenopalatine syndrome."

(4) *Neuralgic.*—Irritation of branches of fifth or other scalp nerves—Trigeminal neuralgia ; cervical caries (occipital).

(5) "*Rheumatic.*"—Inflammation of muscle or aponeurosis of occipito-frontalis — Myositis ; "muscular rheumatism."

Headache of extracranial origin may be part of a rigeminal neuralgia when this is due to some irritant cting on the fifth nerve outside the skull, or may ccompany any process which causes a neuritis of he scalp nerves. Pain of this sort differs from nost other forms of headache in being sharp and radiating. It is accompanied by a superficial tenderness along the course of the affected nerves.

Summary.

To recapitulate, these three main groups based on anatomy correspond with three main clinical varieties typified in the following three examples :—

In supraorbital neuralgia (Group 3, extracranial) the patient complains of a pain which shoots upward into the forehead, and the maximum tenderness will be found over the nerve. Pressure near the supraorbital notch will increase the severity and area of the pain.

In supraorbital frontal sinus headache (Group 2, cranial) the pain is fixed, dull, and may be throbbing ; the maximum tenderness is usually on the floor of the sinus under the inner third of the supraorbital margin. Superficial tenderness is not so marked, and pressure over the supraorbital notch has no definite effect.

In supraorbital headache of intracranial origin (Group 1) there is no tenderness, though there may be hyperæsthesia to finer skin tests.

That is what I believe to be the "anatomy of headache." It does not rest on definitely proved facts, but it is put forward as a useful working hypothesis.

THE TREATMENT OF SCARLET FEVER BY EUCALYPTUS OIL AND CARBOLIC OIL VERSUS ISOLATION.

By G. GUSHUE-TAYLOR, M.B., B.S. LOND., F.R.C.S. ENG.,
PRINCIPAL MEDICAL OFFICER TO DR. BARNARDO'S HOMES AND HOSPITALS.

MY experience of scarlet fever extends over two periods : from 1910–11 as resident medical officer at Her Majesty's Hospital, Dr. Barnardo's Homes, then under the supervision of the late Dr. Robert Milne ; and from July, 1920, up to the time of writing, as one of the medical officers of the Homes. During the former period the treatment of the disease by inunction of the skin with eucalyptus oil and by the application of 10 per cent. carbolic oil to the tonsils and pharynx was accepted without question. The number of cases then seen was less than six. During the past three years, as a result of experience of over 280 cases, I have been led to reject this method. This finding has been for me a most unpleasant one, because it brought me into opposition to a mode of treatment instituted by an honoured personal friend ; for several months before his lamented death we had been in communication upon the subject, and I had hoped that at the close of one year's treatment by isolation a joint pronouncement could have been made. I should now prefer not to enter upon a discussion of such a nature, but am impelled by the following considerations. I have been repeatedly asked by medical officers of health and others for an opinion on the treatment ; the three years' records in my hands contain facts of vital public interest ; the method which has failed in my practice is still being used by others, as at Tottenham and Heston,[1] and only by the collation of records of cases and epidemics can truth be elucidated. The late Dr. Milne[2] has written : "Of course, if the new mode of treatment proposed will not stand the severest tests, the sooner its failure is declared the better." At a meeting of the Epidemiological Section of the Royal Society of Medicine the chairman read a note from Dr. John C. Thresh[3] expressing his opinion : "The enormous pecuniary and other advantages which would accrue to the community if Dr. Milne's claims were substantiated, as he believed they could be, led him to hope that some means might be devised whereby the treatment could be tested under conditions which would render the results conclusive." Such statements as the above have encouraged me to investigate the treatment. The results here recorded have convinced me that the claims made cannot be sustained, and have led me to agree with the criticisms of Dr. E. W. Goodall,[4] one of which is that it has not been shown that the eucalyptus treatment has anything to do with the loss of infectiousness.

During the past 50 years the virulence of scarlet fever has steadily declined, as evidenced by the drop in fatality from about 700 per million of living persons in 1871 to 40 per million in 1921. During this period great advances have been made in public health and hygiene which have a bearing upon rates of mortality. Any imagined benefit seeming to accrue from a specific treatment of the disease during this period may be accredited to the treatment without recognising the fact of diminished morbidity. In my opinion the supporters of the eucalyptus treatment have fallen into this error.

In what follows I give considerable detail, so that the reader may be able to follow clearly the steps by which conclusions have been reached.

The Girls' Village Home, Barkingside, where the cases occurred, stands in its own grounds of 64 acres, and consists of 67 cottages, of which 63 are occupied by children, each in charge of a foster-mother. The accommodation of the cottages varies: most of them have 16, 20 or 25 girls each, there being a smaller number with 12 and 9 girls each. Excluding the receiving house, accommodating 50 girls, and one cottage of 20, used as an accessory receiving house, the population of the village is—

Children under 5 years of age	12
Children between 5–15 years	930
Girls over 15 years	284
Total	1226

The village has its own schools, church, and laundry. It is very difficult accurately to ascertain the number of children protected by a previous attack of scarlet fever. About 750 attend school daily. All attend church on Sunday. All except the younger ones attend an evening service on Wednesday, so that opportunities for transmission of infection, in order of probability, would be: (1) in the cottage, (2) in school, (3) in church, (4) at play, (5) from outside the village, by children going out or visitors coming in.

Frequency of Return Cases.

For the purpose of the present article reference will be made only to group (1) of the preceding paragraph. A return case is defined as scarlet fever occurring within a month in a cottage to which a child recently treated for the disease has returned. No distinction has been made between a month of 30 or 31 days. If there be an error in this reckoning, it is a constant factor over the whole period. Such a return case may not have arisen from the cottage; it may have arisen from one of the other possible foci, or from some focus unknown.

Upon this subject of return cases Dr. F. M. Turner[5] gave as his conclusion: "The alleged return cases include some coincidences as well as true cases, but the proportion of the former is small. Among scarlet fever outbreaks arising after the discharge of scarlet fever cases, the proportion is probably less than 10 per cent." Some authorities adopt a longer period than one month—viz., six weeks up to three months. Any patient who on discharge from hospital infects, or is alleged to have infected, another is referred to as the "infecting case."[6] Both the return case rate and the infecting rate will be given. In those cottages in which are two or more infecting cases, only one will be counted unless an interval of over one month elapsed between the first infecting case and the second return case, the latter then being reckoned as having arisen from the second infecting case.

A tabulation made of the incidence of scarlet fever in the village during 1921 showed an unusually large number of return cases. This suggested the tabulation of all previous outbreaks of the disease for purposes of comparison and to seek a cause for these return cases. The statistics of earlier years are from the infirmary admissions book, which contains a record of admission and discharge dates with diagnosis. In those days the medical officer was not given the amount of assistance which he obtains at the present time, consequently the records are not so full as in recent years. Some patients were treated in their own cottages; details of these cases are not available, which fact may account for a discrepancy in some of my figures compared with those published by Dr. Milne. From 1904 to 1910 patients were treated in three or more cottages used as hospitals, and subsequently in the new hospital, a modern building composed of three wards of 20 beds each and six wards of one bed each.

History of Scarlet Fever in the Village Home, 1902–1923.

The following paragraphs give the history of scarlet fever in the Girls' Village Home from 1902 onwards:—

1902–3.—Three cases each year; all were removed to the Ilford Isolation Hospital. No return case.

1904–5.—From Dec. 16th, 1904, to Nov. 18th, 1905, there were 105 cases. Of these 19 were removed to the Ilford Isolation Hospital; 78 were treated in the Village Home Hospital Cottages; of 8 I can find no record beyond the fact of notification. In reporting this outbreak, the late Dr. Milne wrote: "The most careful separation of the infected children and isolation of those who had been exposed was carried out." This quotation leads one to infer that up to 1905 Dr. Milne had not put into wide use in institutional practice his method, later recommended, of short-period treatment without isolation. These 78 patients were detained in hospital cottages on an average of 52·5 days each. There was only one return case, a rate of 1·2 per cent.

1906–7.—Two and three cases respectively; all removed to the Ilford Isolation Hospital. One return case.

1908–9.—From August 27th, 1908, to Nov. 10th, 1909, there were 31 cases, of which 3 occurred in the receiving house. The first 4 cases were removed to the Ilford Isolation Hospital. Of the 24 remaining cases no record can be traced of 5, which were probably nursed in their own cottages, leaving 19 treated in hospital cottages. Of the latter, one was detained in hospital seven months, one 50 days, one 39 days; the remaining 16 were detained on an average 19 days each. Among the 19 cases can be traced 3 infecting cases causing 5 return cases, giving an infecting rate of 15·7 per cent., and a return case rate of 26·3 per cent.

1910.—Nine cases, two of them in the receiving house; one was nursed in her own cottage, and six in hospital for 32, 28, 19, 75, 22, 191 days respectively. No return case.

1911.—Five cases, detained in hospital for 14, 20, 37, 47, 99 days respectively. No return case.

1912.—One case at the gate house, probably nursed in that house.

1913.—Four cases, three detained in hospital 10, 26, and 142 days respectively. No record of the remaining case. No return case.

1914.—Six cases, three in the receiving house, the other three detained in the hospital on an average 36 days each. No return case.

1915.—Seven cases, all detained in hospital on an average of 30 days each. No return case.

1916.—One case detained in hospital 20 days. No return case.

1917.—Two cases, one in the receiving house, the other detained in hospital 33 days. No return case.

1918.—Seventy-six cases occurred in cottages. They were treated in hospital, not isolated from children suffering from other diseases. The average stay of each in hospital was 12 days. In this year, in 21 different cottages, there were 35 return cases (46 per cent.). Among these, 24 infecting cases can be traced, an infecting rate of 31·5 per cent.

1919.—Ten cases, all detained in hospital on an average of 15·4 days each. One return case (10 per cent.).

1920.—Fifty cases in cottages, detained in hospital on an average of 16 days each. Four return cases occurred (8 per cent.). The infecting rate was also 8 per cent. I cannot say why the return cases were so much fewer in this year than one would have expected. In his text-book on Medicine, Osler[8] has said with reference to scarlet fever: "No one of the acute infections varies so greatly in the intensity of the outbreaks. . . . In some years it is mild, in others, with equally widespread epidemics, it is fearfully malignant."

1921.—In the cottages and among the nursing staff 133 cases occurred, 6 others were admitted from outside homes in Hackney and Stepney, and 19 occurred in the receiving house, making a total of 158 cases. Only the cottage cases will be referred to, as the subject here is return cases from the cottages. These 133 patients were detained in hospital on an average of 19·5 days each. There were in 14 different cottages 35 return cases (26·3 per cent.). There were 21 infecting cases, an infecting rate of 15·7 per cent. From Jan. 1st to March 20th, 1922, there were six return cases out of 24 patients discharged. On March 22nd all scarlet fever patients were isolated in one ward, and kept in for six weeks or longer, until nose and throat were clear of evident disease. The eucalyptus and carbolic oil treatment was used as heretofore. An immediate drop in incidence and return cases took place, only one return case having occurred up to March 21st, which completed one year of isolation treatment.

During the year from April 1st, 1922, to March 31st, 1923, there were 27 village cases, among which are included one nurse and two girls in the hospital where they were treated. There was one cottage return case. To compare with a complete year of the non-isolation treatment, the following statistics are given. During the year April 1st, 1921, to March 31st, 1922, there were 124 patients with scarlet fever, among them 35 return cases, a rate of 28·2 per cent.; there were 23 infecting cases, giving an infecting rate of 18·5 per cent. In the following year, from April 1st, 1922, to March 31st, 1923, by no other change than keeping the patients isolated on an average of 54 days each, the incidence has been reduced immediately to 27 cases with one return case, a drop from 28·2 per cent. to 3·7 per cent. The return case was from a child kept in 40 days. Had she been detained a week or ten days longer the result might have been different; on the other hand, it might not.

It should be stated that on July 11th, 1921, the work was begun of renovating the drains in the village. By April 1st, 1922, 36 cottages had drains completed. During the following year, till March 31st, 1923, there were 16 fresh cases of scarlet fever in these cottages, as against eight cases in those in which the drains had not been finished. These figures would indicate that improvement in drainage had not been a serious factor in leading to the reduction in incidence of the disease.

Comparative Considerations.

So as the more easily to compile tables and make comparisons with other areas, the year of isolation will be dated from April 1st, 1922, to March 31st, 1923. Bearing this fact in mind with regard to the final two lines in Table A—the table contains some of the recorded facts relating to outbreaks of ten cases or over—from it the general truth emerges that, between a period of 10–50 days, the longer the period of detention the fewer the return cases. After a detention of 50 days it might be wise to transfer the patient to a non-infectious ward to avoid his mucous membranes having sown on them a fresh infection by acute patients recently admitted.[9]

TABLE A.

Year.	Total village cases.	Detention in hospital (days).	No. of return cases.	Percentage of return cases.	Infecting rate.
1904–5 ..	78	52·5	1	1·2	1·2
1908–9 ..	19	23·8	5	26·3	15·7
1918 ..	76	12·0	35	46·0	31·5
1919 ..	10	15·4	1	10·0	10·0
1920 ..	50	16·0	4	8·0	8·0
1921–2 ..	124	19·5	35	28·2	18·5
1922–3 ..	27	54·0	1	3·7	3·7

TABLE B.

—	April 1st, 1921, to March 31st, 1922.		April 1st, 1922, to March 31st, 1923.	
	No. of village cases.	% at village home of total cases in Ilford.	No. of village cases.	% at village home of total cases in Ilford.
April ..	13	26	4	22
May.. ..	18	60	4	16
June ..	13	41	4	21
July.. ..	11	36	4	16
August ..	6	31	1	12
September	10	35	3	15
October ..	17	40	1	11
November	3	9	4	28
December	12	24	2	15
January ..	15	34	1	11
February	9	30	2	25
March ..	8	28	*0	—

* In March there were 7 cases in Ilford.

Table B illustrates the drop in incidence in the village home as compared with that in the whole area of the Ilford Urban District Council, which includes the village home. In the year of more prolonged isolation, the village cases were a much smaller percentage of the total cases in the Ilford district than in the previous year. In both years eucalyptus and carbolic oil treatment was applied.

I cannot explain the irregular drop to three in the number of cases in November, 1921. Search for an explanation has been fruitless. The admissions for tonsillitis in October, November, and December, 1921, were 18, 14, 14 respectively.

Table C gives the percentage drop in incidence in the village home in the prolonged isolation year compared with the previous year, and similar figures have been prepared showing the drop in the M.A.B. area. The figure has been obtained thus: in one year were 14 cases, in the next year 4 cases, a drop of 10, which is a 71·4 per cent. decline. The M.A.B. figures show a decline due to the abating of the epidemic. There is a much greater decline in the village home figures, this decline being composed of the additional factor of more prolonged isolation of patients in hospital.

TABLE C.

Spread of Infection in Wards.

In spite of the continued use of eucalyptus and carbolic oils, there was a spread of infection to susceptible persons. This is illustrated by the following examples:—

(*a*) *Nurses.*—(1) Nurse A., while nursing in a ward, between March 5th and 11th, 1921, attended six fresh cases of scarlet fever. On the 12th she was ill with the disease. (2) Nurse B., a new probationer, went on duty on Feb. 16th, 1922, in a ward where several patients had scarlet fever. On the 22nd she took the disease. (3) Nurse C. worked in a house where was a child who had scarlet fever on August 12th, 1921, and who was detained in the same house until Oct. 14th, 1921; the nurse took scarlet fever on Sept. 11th. Her duties would lead her into frequent contact with the child. (4) I have notes of four other nurses who have taken scarlet fever under similar circumstances during the past five years. Our nursing staff rarely exceeds 18.

(*b*) *Other Patients.*—(1) A girl aged 8 admitted with tuberculous peritonitis on Feb. 26th, 1921. On March 7th she was very ill with broncho-pneumonia. On the 10th scarlet fever supervened, followed three days later by death, which in my opinion was hastened, not caused, by scarlet fever. In the same ward were patients with scarlet fever being treated by eucalyptus and carbolic oils. (2) Girl aged 12 admitted with follicular tonsillitis on Nov. 29th, 1921; on Dec. 9th up and about the ward; on the 12th scarlet fever. In the same ward were six other children being treated for scarlet fever. (3) Girl aged 13 admitted with tonsillitis on Jan. 24th, 1921. On Feb. 4th up and about the ward; on the 9th scarlet fever. In the same ward was a case being treated for scarlet fever.

I have notes of other very similar cases illustrating this point. It must be understood that all these patients were being treated with eucalyptus and carbolic oils from the first suspicion of scarlet fever—that is, on the onset of sore throat. Some of these cross-infections may be coincidences, some may possibly be from outside sources, but it is surely against common sense and the laws of evidence to accept a bare possibility on the one side against a strong probability on the other.

Complications.

The use of eucalyptus oil and carbolic oil did not prevent the onset of secondary complications. Table D gives those in the village homes among 62 patients in 1922, and for comparison those occurring in the Ilford Isolation Hospital under the care of the medical officer of health, Dr. A. H. G. Burton, who has kindly given me his statistics :—

Table D.

Complications of Scarlet Fever in 1922.

—	Percentage of Village Home cases.	Percentage of Ilford Isolation Hospital cases.
Albuminuria	6·4	9·8
Adenitis	19·3	24·6
Broncho-pneumonia and death	1·6	nil
Endocarditis	nil	nil
Jaundice	nil	1·2
Otitis media	4·8	8·02
Rheumatism	nil	4·9
Rhinitis	4·8	nil or not stated.

Remarks.

The criticism will be raised that the treatment has not been carried out in the proper manner. In reply it should be pointed out that the matrons in charge of institutions in which I observed the treatment to fail had been there for several years under the late chief medical officer, Dr. Milne, and are still in charge of their nursing staffs. They agree that the application of the method had not changed in any way since the retirement of Dr. Milne towards the end of 1919; but in fairness to them it must be recorded that they retained their belief in the treatment while my faith failed. It was suggested that the eucalyptus oil was inferior to that used in previous years; a specimen was sent to the Clinical Research Association, Ltd., for examination, and the following report was returned: "March 14th, 1922, No. 8987. This is a specimen of genuine eucalyptus oil of very good quality. It conforms to all the British Pharmacopœia tests and contains 77 per cent. of cineol."

If the figures given of the period of detention in hospital of cases from 1910 to 1917 be examined, it will be found that they are not, on the whole, short; further, these cases are too few for any valid conclusion to be drawn from them. A striking fact is seen on examining the years 1904–5 and 1922–3 as set forth in Table A.; both periods have one return case, and a prolonged detention in hospital; the intervening years have a shorter period of detention, and many return cases.

It is generally accepted that in scarlet fever the desquamation of the skin is not infectious, but that the discharges from mucous surfaces are infectious, especially during the more acute stages of the disease. In a convalescent patient any discharges from the ear, nose, or throat, are to be regarded as infectious; and a patient should not be allowed to mingle with healthy children until these parts show no sign of active disease.

It would be sound treatment if all discharging ears, which did not clear up in eight to ten weeks after the throat, nose, and naso-pharynx had been treated were subjected to an incomplete mastoidectomy along the lines of the Heath operation. This would conserve the hearing, and remove a focus of disease in a potential carrier. Convalescent patients from scarlet fever who have hypertrophy of the tonsils which show signs of disease should have the tonsils enucleated. If the tonsils be atrophic but diseased they should be removed. Some of the indications for the removal of tonsils and adenoids after scarlet fever are mouth-breathing, rhinorrhœa, otorrhœa, an unhealthy angry-looking surface of a diffluent tonsil, and enlargement of cervical glands after rheumatism complicating the disease. The application of carbolic oil by swabbing to the throat is, in my opinion, of doubtful value, and may be harmful. The tonsils and fauces are acutely inflamed; to swab such an area not infrequently causes an abrasion of mucous membrane with slight bleeding, especially in young and nervous children, thus opening up fresh paths for the entry of pathogenic organisms. I am quite aware that carbolic oil has a local analgesic action which is sometimes appreciated, but I am not sure that the patient would not be more benefited by a hot inhalation of tinct. benz. co. or carbolic acid, by the use of which no trauma would be caused, but which would act as a hot fomentation to the inflamed throat. In a severe case of scarlet fever the infection invades, not only the tonsils and pharynx, but probably the nasal cavities and accessory sinuses, Eustachian tube, larynx, and trachea; hence the futility of seeking to apply any antiseptic to the infected area, beyond the cleansing of the mouth which is routine in all cases of fever.

Conclusions.

1. The use of eucalyptus oil applied to the skin, and of carbolic oil to the throat in the treatment of scarlet fever (*a*) does not prevent the occurrence of return cases, (*b*) does not prevent the infection spreading to susceptible patients and attendants during the course of treatment, (*c*) does not prevent secondary complications.

2. The number of return cases varies inversely as the length of the period of detention, when this period is up to about eight weeks.

3. All cases of scarlet fever should be isolated for at least eight weeks. They should not be allowed to mingle with other children until the ear, nose, and throat appeared healthy.

I wish to express very cordial thanks to Dr. A. H. G. Burton, the medical officer of health for Ilford, for assistance in obtaining statistics used in some of the tables, and for very willingly supplying information on many points discussed in this paper.

GASTRO-DUODENOSTOMY *V.* GASTRO-ENTEROSTOMY IN THE TREATMENT OF CHRONIC DUODENAL ULCER.

By E. R. FLINT, F.R.C.S. Eng.,
ASSISTANT SURGEON, GENERAL INFIRMARY, LEEDS.

In spite of all that has been written about the medical treatment of duodenal ulcer, there can be no doubt that surgery is the safest and the most expeditious remedy for this disease as we see it at the present day. Possibly earlier recognition of the condition and of the primary infecting focus will render surgical treatment of the ulcer unnecessary. At present medical treatment is more dangerous than surgical. Acute perforation and hæmorrhage only occur after one course and usually after many courses of medical treatment; a surgeon may be called in to deal with these emergencies and the patient may succumb, but the death must be placed to the account of medicine, for surgical treatment before the catastrophe would almost certainly have prevented it, and the death-rate after gastro-enterostomy in the chronic stage of the disease is negligible.

When we consider the progress of a patient after surgical treatment we find that most surgeons state that they cure between 80 and 90 per cent. of their patients, and undoubtedly gastro-enterostomy, accompanied by local treatment of the ulcer and eradication of a supposed primary infecting focus, is a highly satisfactory operation. Whether it is true that so high a percentage of cures is effected is perhaps an open question, and depends on the definition of cure. Indiscretions in diet or habits, in a fair proportion of these cases, are apt to cause temporary discomfort in the form of flatulence and a feeling of uncomfortable distention, which may be quickly recovered from, but serves to show that the reserve territory, as it were, between health and disease has been considerably reduced, and that though the ulcer has been cured in that there are no recurrences of ulcer attacks, the remedy has exposed the patient to inconveniences to which a normal person is not liable.

The progress after medical treatment is almost invariably a recurrence of the ulcer attacks; there is remission of varying duration, but not cure in any sense. Medical treatment has to be so prolonged, and is so irksome, that the patients will not be bothered with it once the attacks have thoroughly subsided. However, it is my intention not to contrast medical and surgical treatment further, but rather to criticise surgical opinion in its relation to duodenal ulcer—that is to say, whether it is right to regard gastro-enterostomy as *the* operation to perform.

Gastro-duodenostomy: Trial Advocated.

We have become so accustomed to treating chronic duodenal ulcer by this operation that the mention of the one almost automatically calls up in one's mind a vision of the other. In the earlier days of the treatment of this disease gastro-enterostomy had many rivals, but it gradually ousted them all, as the results achieved were found to be so much superior to those attained by any other method which received an adequate trial. There is one operation, however, which I think has never had such a trial, and which in the opinion of a few surgeons still holds its ground as a successful rival to gastro-enterostomy, but only under exceptional circumstances. I refer to gastro-duodenostomy. The present-day surgical opinion may be briefly stated as follows. With a favourable disposition of the parts gastro-duodenostomy may be performed, and the results will be as good as those after gastro-enterostomy; but gastro-enterostomy will have to be done in the vast majority of cases, because the duodenum cannot be sufficiently mobilised. The operation, therefore, is only performed in some 4 or 5 per cent. of cases at the most. Since 1894, when Jaboulay first did gastro-duodenostomy, this has been, generally speaking, the recognised surgical opinion, though no one, so far as I know, has done the operation in a consecutive series of cases.

Technique.

Surgical text-books give the scantiest attention to this operation, when they mention it at all. Probably anatomists are partly responsible, because they have always taught that the duodenum is a fixed organ ike the ascending colon, whereas both organs have a considerable degree of mobility; the ascending colon practically always, and the second part of the duodenum not infrequently, has a definite mesentery. I venture to say that after dividing the peritoneum on the posterior abdominal wall to the outer side of the duodenum very little further manipulation will suffice to bring the duodenum to the surface of the usual abdominal wound used for stomach operations, not only where the duodenum is normal, but even when a duodenal ulcer is present. That this is no exaggeration is shown by the fact that in the last 53 cases of duodenal ulcer I have been able to perform gastro-duodenostomy in 50, and had to employ gastro-enterostomy only three times—twice because of dense pathological adhesions, and in the other case (a boy aged 12) because there was such a large inflammatory mass around the ulcer that I thought it wiser to leave the neighbourhood alone. I may come across a long series in which it will be inadvisable to do gastro-duodenostomy, but those cases on which I have already done it have been the type of duodenal ulcer usually met with. I think this operation will be possible in some 90 per cent. or more of cases, and that consequently gastro-enterostomy will only need to be performed in less than 10 per cent.

After mobilising the duodenum in the manner already indicated, and after dealing with the ulcer by cautery or otherwise, an anastomosis is made between the second part of the duodenum and the anterior surface of the stomach close to the pylorus; the suturing is done exactly as in gastro-enterostomy. The raw area left on the posterior abdominal wall can easily be covered by peritoneum or omentum.

The only impediment to the more frequent employment of this operation is the supposed difficulty in mobilising the duodenum, for if one asks a surgeon whether he performs this operation he answers that he does in suitable cases, implying that he regards it as equal in efficiency to gastro-enterostomy when it can be done. I maintain that it can be performed in nearly every instance, and with no more risk to the patient than that attached to gastro-enterostomy. If I am right in this, I think there are material advantages to be derived from employing it more frequently.

It is rather difficult to compare the results after gastro-duodenostomy with those after gastro-enterostomy; the latter operation has been performed so infinitely more often that it is only natural that one should see more cases requiring further treatment than after the former. Many surgeons have done gastro-duodenostomy on rare occasions, and in the aggregate this means quite a large number have been performed, yet I have never heard of a surgeon regretting that he did the operation, and I have never seen a case return for further treatment of any sort. It is quite true that gastro-enterostomy gives very good results, but no surgeon who sees many stomach cases can say that he has not had many, either of his own or someone else's, return to him incompletely cured, sometimes, indeed, worse than before. No case has been reported of the occurrence of an ulcer at the line of the anastomosis after gastro-duodenostomy; this complication occurs in at least 2 per cent. of cases after gastro-enterostomy. The patient is then in a much worse state than before the original operation, for this disease is more crippling, and a very formidable operation is necessary to cure it.

It is so unlikely that an ulcer will ever be seen at the anastomotic line after gastro-duodenostomy that when I have a gastro-jejunal or jejunal ulcer to deal with I excise it, suture the openings in the stomach and jejunum, and do gastro-duodenostomy. I believe this will become the usual treatment, until the performing of gastro-duodenostomy in the first instance renders an operation for these anastomotic ulcers unnecessary. Hitherto, gastro-duodenal ulcers have been treated by excision and a new gastro-enterostomy, or better by partial gastrectomy; neither of these can be relied upon to prevent another ulcer of the same kind returning, for I have seen one certain case, and I think a second, in which a gastro-jejunal ulcer appeared after partial gastrectomy.

Other Considerations.

Two further considerations may be of importance. In performing gastro-duodenostomy one does not interfere with the small intestine below the great omentum, whereas, of course, in gastro-enterostomy one does, and it is usual to find adhesions of some coils of the small intestine to the neighbourhood of the anastomosis, which, at any rate, cannot be a desirable state of affairs. The other point is, that wherever a new opening is made it will produce some tethering of the stomach, and it would seem to me better that this should occur at a point normally somewhat fixed as the pylorus is, rather than on the freely moving posterior surface of the stomach.

From a physiological point of view gastro-duodenostomy should be the better operation, as it is a much nearer approach to Nature's plan. It may be said that a gastro-enterostomy opening being at the lowest point of the stomach will drain this organ more effectively, but the stomach of a patient with a duodenal ulcer is either a shallow high-lying one, or a big hypertrophied organ with powerful muscular contractions. It is only reasonable to suppose that Nature, having placed the pylorus at the most favourable point, will continue to utilise an opening as near the normal one as possible to better advantage than one at some distance away, as is the gastro-enterostomy opening.

It is still early to speak of the results in my series, as these cases refer to a period of only a year, but up to the present the post-operative progress of the patients has been most satisfactory—certainly as good as, and I think better than, after gastro-enterostomy. The question of mortality need not be brought into the discussion; there have been no deaths in my series, and, of course, there is practically no death-rate for gastro-enterostomy; it is less than 1 per cent.

I believe gastro-duodenostomy to be both more natural and physiological (if one may use the term in connexion with any short-circuiting operation) than gastro-enterostomy, and I believe it will be found possible to perform it in all but a very small percentage of cases. It should be remembered, too, that in a small percentage of cases it is also impossible to do posterior gastro-enterostomy, either because of a very small stomach in a fat patient, or because the lesser sac, or that part of it which is required for the operation, is obliterated by adhesions. Anterior gastro-enterostomy is then usually done, and this is not a desirable operation.

Clinical and Laboratory Notes.

A CASE OF ACUTE MYELITIS, WITH RECOVERY.

By F. Joselin Jauch, M.R.C.S. Eng.,
LATE RESIDENT MEDICAL OFFICER, LONDON TEMPERANCE HOSPITAL.

It is well known that complete or even partial recovery from acute myelitis is rare, death usually occurring from ascending urinary infection, trophic disturbances, or pulmonary complications. The following case is perhaps unique, in that the patient, who showed all the signs and symptoms associated with that condition, suffers after nine months from no serious effects, with the exception of some difficulty in retaining his urine.

History.—A male, aged 47, engaged in secretarial work, was seized on Oct. 25th, 1922, with very severe pain in the scapular region at about 7.30 P.M., followed two hours afterwards by severe pains in both feet. He went to bed shortly afterwards. On waking up in the morning the pains in the back were less, his feet still ached, and he had lost sensation and power of movement of his lower limbs. His bowels were confined and in the evening he observed incontinence of urine. He had been in the Navy 8½ years; there was no history of syphilis. He had had gonorrhœa at 17 years of age and "Malta flux" at 30, otherwise he had had no serious complaints. He was married and had a healthy child of 5; his wife was apparently healthy and there had been no miscarriages. He was sent to the London Temperance Hospital on the 30th, four days after the onset of the condition, with a diagnosis of acute intestinal obstruction.

Condition on Admission.—Pulse 120, respiration 30, temperature 96·6° F. Patient of good physique, tongue thickly coated; abdomen distended, with some rigidity, especially in upper half; retention of urine with overflow, and complete confinement of bowels. Nervous system showed the changes usually associated with complete transverse myelitis; complete anæsthesia to heat and touch from the xiphisternum downwards; above this area, which extended upwards and backwards to the outer edge of the erector spinæ, there was an ill-defined band of hyperæsthesia. On the right-hand side the anæsthetic area reached up to the umbilicus only. Paralysis of the lower limbs and lower abdominal wall was complete; no control over the rectal and urinary sphincters. Knee-jerks, Achilles-jerks, plantar and abdominal reflexes were absent. Right pupil showed some irregularity in outline, but both sides reacted normally. Trophic changes were evidenced by presence of pressure ulcers in lower dorsal and sacral regions, as well as over both heels. Repeated examination of the cerebrospinal fluid, which on the first occasion flowed at a slightly increased pressure, showed no macroscopic, cytological, or chemical changes; it was sterile, and the Wassermann and blood reactions were repeatedly negative. The other systems appeared normal.

Course of Case.—Sensation gradually returned, and on Nov. 3rd the hyperæsthetic area had disappeared, superficial and proprioceptive sensation had been re-established, though deep pressure was painful. Some spasticity of the lower limbs was present. On the 10th very slight effusion into the knee-joints occurred, also, later, some periarticular swelling of the right metacarpo-phalangeal joint; these conditions, however, subsided entirely. At this time a very small degree of abduction and adduction at the hip became possible, as well as flexion and extension at the knee and ankle. The knee-jerks and abdominal reflexes were just obtainable. Improvement was maintained, and on Jan. 3rd, 1923, the patient got up and was able to stand on his legs. Some control over the rectum had been established, and the patient managed to retain his urine for one to two hours.

Partial Recovery.—The patient was discharged on March 7th. Sensation was normal; walking was possible with the aid of a stick; the gait was shuffling in character; there was some difficulty in turning about. The knee-jerks were slightly exaggerated; the plantar reflexes were of the extensor type. No Rombergism or ataxia was present. Control over the rectum was almost complete. As regards micturition, the patient had about two minutes' warning, after which the bladder emptied reflexly; it was necessary, therefore, to wear a urinal. He is now able to stand seven to eight hours a day, and can walk six to seven miles quite comfortably. Occasionally he has some cramp in his feet; the urinary mechanism has improved, and there has been a gain in weight to the extent of 22 lbs. Treatment was symptomatic; massage and faradism were commenced very early.

For permission to publish this case I am indebted to Dr. Porter Parkinson, senior physician to the hospital.

AN UNUSUAL CASE OF CHICKEN-POX.

By H. Cooper Pattin, M.D., D.P.H. Camb.,
MEDICAL OFFICER OF HEALTH, CITY OF NORWICH.

On a certain Monday my assistant, Dr. G. L. Leggat, was taking a school clinic, and experienced a shock when a woman brought into the room a girl, aged 11, with what, at first sight, looked like small-pox. After careful investigation of the rash, which in distribution was certainly that of small-pox rather than of chicken-pox, noting that it was at varying stages, that the girl had four good vaccination marks, that she appeared to be quite well, and learning that she had never been ill, Dr. Leggat diagnosed the case as one of chicken-pox and referred the case to me. Looking at the distribution of the eruption, my first impression was that it was small-pox; but going carefully over the character of the rash and the history, I concurred with Dr. Leggat's diagnosis and agreed that it was one of chicken-pox; albeit the most unusual case I had seen. Whilst there was a generalised distribution of rash it was most abundant on the face, forearms, hands, legs, and feet, some on plantar surface of the latter; it appeared on the flexor as well as extensor surfaces, and was, in places, almost confluent.

The history was this. The girl had been to a school treat on the preceding Thursday, which was a very hot day with a broiling sun, and her face, arms, hands, legs, and feet had been freely exposed to the sun, as also had the back of her neck and interscapular area, where the eruption also was dense. She came home tired, but quite well, and developed some vesicles during the night; at any rate these were very noticeable in the morning; the mother called in no doctor, and in fact only brought her up to the school clinic on the following Monday because she had become alarmed at the further and more profuse development of the eruption; when seen by us many of these vesicles had become pustular and a few had maturated and become encrusted. The girl was never ill at any time.

The explanation we arrived at respecting the unusual distribution of the eruption was that the sun's heat had given rise to some heat erythema of the exposed parts, and that this accidental superficial irritation had determined the profuse character of the subsequent eruption; and this belief has been fortified by a few other cases, but none of so striking a character. Subsequently our diagnosis received confirmation by the occurrence of chicken-pox in a sister 17 days after the appearance of the eruption in the first instance. In Dr. McC. Wanklyn's book on "How to Diagnose Small-pox," on pp. 58–59 there is recorded a strikingly similar case. The point is worth considering when chicken-pox erupts in hot sunny weather.

THREE CASES OF SCURVY.

By ROBERT H. NORGATE, M.R.C.S. ENG.,
MEDICAL SUPERINTENDENT, SOUTHMEAD INFIRMARY, BRISTOL.

DURING the past two years there have been three cases of scurvy under treatment in the Southmead Infirmary, Bristol. Such cases are unusual now that conditions of life are more normal.

CASE 1.—Female, aged 28, admitted Nov. 23rd, 1922, from a Poor-law institution, where there is always an abundance of green vegetables in the diet; the patient, however, always refused to take vegetables and took an excess of salt with her food. Temp. 98·6° F., pulse 94, resp. 16. Spongy gums, teeth buried in them; hæmorrhages in legs and follicular keratosis on both arms and legs; skin very dry, with a stained appearance; patient thin and haggard. Some fœtor of the breath; no hæmorrhage in urine or stools; no albumin. Green vegetables were insisted upon at each meal and oranges were given. She made a rapid recovery.

CASE 2.—Male, aged 52, a labourer, sent in on April 20th, 1923, as a case of iliac thrombosis complicating tabes dorsalis; no abdominal pain; right leg very red, with swollen spots; hæmorrhages in the tissues, several purpuric blotches on both legs, and follicular keratosis. Typical signs of tabes; no hæmorrhage in stools or urine; both iliac arteries and right popliteal artery pulsating; history of leg swelling now and again, and this time four days. Patient was kept in bed at rest and plenty of green vegetables and oranges given daily, and salt decreased. Patient has only one tooth, but the gums are very red and spongy and bleed easily. He was able to get up in a month and was discharged on June 2nd, all swelling and signs of hæmorrhage having disappeared. He had been living on tinned foods, with no vegetables; he had been out of work for a considerable time, owing to tabes, and was unable to walk far.

CASE 3.—Male, aged 58, a clerk, had seen better days but ad recently been out of work. Sent in as a case of heumatism on June 2nd, 1923; seen by assistant medical officer and diagnosed as "iliac thrombosis." For two weeks he right leg had been swollen and there had been purpuric æmorrhages like hæmatomata in muscles of the calf; keratosis on both arms and legs; popliteal vessel pulsating; gums so swollen as to almost hide the teeth, and bleeding easily. Patient had been living in common lodging-houses, eating salt meat and tinned foods with no vegetables, having no facilities for cooking the latter. Lettuce or other greenstuff is very scarce and expensive this year, and not being a tramp patient had not had opportunity of getting t. The case ran the ordinary course. All hæmorrhages ave now disappeared, and he is now well.

On discharge each case was warned as to diet and he necessity of green food.

POST-GRADUATE TEACHING IN LIVERPOOL.—A ourse of clinics under the auspices of the Board of Clinical Studies is being inaugurated for the coming winter. The nderlying idea is to provide each day of the week at .30 P.M. a demonstration of clinical material of interest to he general practitioner. The work is being undertaken by he honorary staffs of the hospitals, both general and special, nd all the hospitals of the city are taking part. Advantage ay be taken of as many or as few of the meetings as may e found practical by local doctors, and the favourable eception given to the preliminary notices suggests that the ffort of the Clinical Board is meeting a real want. The linics will be free.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT PORTSMOUTH.

(*Continued from p. 463.*)

SECTION OF TUBERCULOSIS.

WEDNESDAY, JULY 25TH.

AT the opening session of this section Sir HENRY GAUVAIN (Alton), the President, being in the chair, Prof. AXEL REYN (Med. Supt., Finsen's Medicinske Lysinstitut, Copenhagen) read a paper on the

Artificial Light Treatment

of lupus and other forms of tuberculosis. This treatment, he said, is used in two forms, either in concentrated form as a local application or in non-concentrated form as a light bath. Finsen used the carbon-arc light as the nearest approximation to sunlight, particularly because it contains more ultra-violet rays than the sun, these rays having the strongest effect. The sun-bath treatment, so successfully applied by Bernhard and Rollier, is, because of natural conditions, difficult of application in northern countries and must therefore be replaced by artificial means. The lamps used require to be specially constructed. That for local treatment is a 50-ampère lamp with convergent lenses of rock-crystal for concentration, the heating rays being absorbed by distilled water interposed between some of the lenses. For the light bath 50 to 52 volts are the most advantageous, working with 70 volts on the conducted current, the surplus being necessary for quiet and steady functioning. Glass as an envelope is not used. Where a number of patients require to be treated at the same time 75-ampère lamps are used, the intensity of the light decreasing, of course, with the square of the distance. As to the class of case so treated:—

1. Lupus vulgaris and other forms of skin tuberculosis. In this class the value of the local light treatment is incontestable, and in those patients refractory to it a combined local treatment and the light bath have produced something like 90 per cent. of cures.

2. Surgical tuberculosis. In these cases sinuses, abscesses, &c., the results of treatment have been excellent, more especially when regard is had to the fact that the majority were adults with poor and unhealthy homes, treated as out-patients and chronics. In a large number it is noteworthy that cure has been accompanied by the regaining of free mobility of the joints. The results indeed are as good as those obtained by heliotherapy in mountain heights.

As one would expect, a shorter period of treatment suffices for children than for adults, for affections of the small joints than for those of the large, and for disease of the soft tissues and bones. Tuberculous glands form a special category in which brilliant results have followed treatment by a combination of carbon-arc light, X rays, and light baths alone. It is to be understood, of course, that necessary operative measures for the correction of deformities and ankylosis are indispensable. The good results from treatment are due to the chemical power exercised by the rays of light which produce erythema of the skin, pigmentation, and stimulation of the organism generally, and various investigators have shown that the greatest effect is produced by ultra-violet long-wave rays. The carbon-arc light contains all the rays of the spectrum, whereas the mercury-vapour lamp emits mainly the short-wave ultra-violet rays with little power of penetration. The latter is therefore less suitable for use. The best results are only to be obtained if a pronounced erythema is produced in the earliest stages of the treatment, contrary to Rollier's opinion. As it is essential to employ the relatively deep penetration of the carbon-arc rays the tissues subjected to the process must be made bloodless by compression. Methods of treatment which aim only at producing a superficial effect, as in cases of extensive lupus, will fail.

Prof. Reyn showed several charts and tables and related illustrative examples of the treatment outlined above.

Dr. J. H. **SEQUEIRA** (London) stated that many of those who began to employ the Finsen-light treatment when there was a boom in such methods failed to achieve good results because of lack of technique. Treatment by the concentrated arc light is expensive, and by employing the arc bath the duration of exposure is shortened and the expense is less. Exposure of the whole body also renders the local action more effective. Both local and general treatment should be the method of attack, in which excision, the use of salicylic acid, creasote, and so on, may be helpful in given cases. From an æsthetic point of view the value of the light treatment is considerable. In dry lupus it is the ideal method of treatment and in ulcerative conditions may be of great service. Having employed the treatment for over 23 years he could testify to the permanence of the cures obtained by its aid. The cases contrast with the effects of treating tuberculosis by the indiscriminate use of the X rays—e.g., in lupus, in which ten years after carcinoma may follow, produced solely by the rays. Nevertheless, X rays do produce good effects with occasional short exposures in ulcerative cases. The Finsen-light treatment, besides the local benefit it produces, also improves the general health of the patient, who becomes noticeably bright and alert. Complicating lesions in other parts of the body also heal up, although they have not been locally treated at all. Lastly, the treatment is cheap and costs but 10*d.* per hour to run.

Prof. **SIDNEY RUSS** (London) discussed the wavelengths of the portions of the light spectrum which could be employed, and it was now possible to assign specific reactions to their appropriate wave-lengths. Between 3000 and 2000 (Angström units) waves are readily absorbed by animal tissues, and have a germicidal action, as has been shown by exposing agar plates to the ultra-violet radiation from the tungsten arc. The germicidal action is maintained until a certain wave-length is reached, after which the action is not produced. There is no radiation produced between wave-lengths of 2000 and 3000. They cannot penetrate as much as a millimetre of skin. Between 3000 and 3800 absorption ceases very abruptly, and it is to this region that we must go for effective radiation. Thus full radiation of the sunlight or artificial light is beneficial; if filtered to a wavelength a little less than 3000 benefit is still produced; filtered to get still shorter wave-lengths has no beneficial effect. Those who pigment react favourably to light treatment, which is a necessary part of the treatment. If different artificial sources of light are taken their characteristics differ considerably—e.g., mercury, carbon, &c.—the skin reaction, therefore, depending on the source of the light and the wavelength. It is essential that these characteristics should be ascertained when the results, from an economic point of view, will be justified.

Sir **STCLAIR THOMSON** (London) was impressed by the fact that when he visited Copenhagen it was claimed that 50 per cent. of cases of tuberculous laryngitis were arrested by the light treatment, as he himself by all other methods had only 25 per cent. of arrests. Thus of 500 cases of tuberculous laryngitis treated at Midhurst during the last ten years, 75 per cent. are dead, most of them from general infection. Without doubt, therefore, if the light treatment can produce arrest in 50 per cent. of these cases, and tuberculous laryngitis is the most serious of all complications of the disease, a great step forward will have been taken.

Dr. J. M. **JOHNSTON** (Tor-na-Dee) had used the carbon-arc lamp in two severe cases of tuberculous laryngitis, in one of whom the severe pain was relieved though the disease was advanced. In the other, after six weeks the patient was practically free from pain and all local treatment was stopped. In the treatment of sinuses the results have been remarkably good when all other forms of treatment had failed. He considered that the method, limited though his experience had been, has a definite sphere of usefulness.

Prof. **REYN**, in replying to the discussion, stated his opinion that the Finsen light installation at the London Hospital was the best that he had seen in any country. Two points were insisted upon—technique and general measures in treatment.

The **PRESIDENT**, conveying a vote of thanks to Prof. Reyn, remarked that though light therapy had proved itself of great value in tuberculosis and other diseases the final answer to the whole problem is a clinical one. It is not enough to study the source of the light used in treatment, the patient himself and his individual reactions must also be taken into account.

Dr. J. **GRAVESEN** (Med. Supt., Vejlefjord Sanatorium, Denmark) then read a paper on the present position of the

Surgical Treatment of Pulmonary Tuberculosis.

Modern developments, he said, of surgical treatment applied to cases of pulmonary tuberculosis have followed the practice of artificial pneumothorax. It is a serious drawback to the latter that it and subsequent methods are being used only in advanced cases and are so dependent on a most scrupulous technique, and results must be judged according to the anatomical and physiological possibility of deriving full benefit from the treatment. It becomes necessary to classify the cases with regard to the influence exerted by the presence of pleural adhesions. Tables shown made manifest how frequently adhesions handicap the full benefit of artificial pneumothorax. Classified, the cases fall into the following groups: (1) Cases with complete pneumothorax: (*a*) without adhesions, (*b*) with localised, extended adhesions; (2) cases with incomplete pneumothorax with larger adhesions; (3) cases with universal adhesions—no pneumothorax practicable.

1. Cases with complete pneumothorax without noteworthy adhesions generally prove successful with marked improvement in symptoms, &c., and, in the absence of complications, no further operation is done. Treatment is individual and the optimum pressure and length of interval between insufflations settled according to the clinical indications. In complications, particularly pleuritic effusions, special care is taken so as not to influence the result of treatment. As to the relationship between pneumothorax and ordinary pleurisy with effusions it is found that the addition of insufflation to ordinary aspiration has checked the development of adhesions and allowed the performance of a pneumothorax successfully.

2. Cases with complete or almost complete pneumothorax, but with localised, extended adhesions—thoracoscopy with cauterisation. The only method to be recommended for endopleural operation and the removal of adhesions is that of Jacobaeus, a method of both diagnostic and therapeutic importance. The thoracoscopic method of Jacobaeus enables one to obtain a direct localisation of adhesions, connecting or supplementing that obtained by the X rays. By cauterisation with a platinum wire introduced through a separate cannula adhesions have been destroyed and successful pneumothorax induced. It is a procedure of permanent value in a limited number of pneumothorax cases with string-like or membrane-like adhesions. The cauterisation of surface adhesions may involve the risk of hæmorrhage and the opening of tuberculous foci and cavities with a consequent infection of the pleura, the most serious complication hitherto encountered. Only a weak, redly-glowing galvano-cautery is used. To sum up the results of the author's experience—none of the technical or clinical complications is of such grave importance as to warrant abandoning the method in suitable cases.

3. Artificial pneumothorax not possible to any satisfactory degree—thoracoplasty. The indication for the performance of this method arises when, in cases fit for lung collapse treatment, careful attempts at artificial pneumothorax have failed. Owing to the greater risks involved, however, a more pressing

need of collapse and a more reliable condition of the diseased lung are demanded. Before doing the operation we have to consider (1) whether a partial or a complete thoracoplasty should be done; (2) or the operation done in one, two, or more stages. (1) Partial thoracoplasty may be considered sufficient, either when the affection—e.g., a cavity—is localised to a limited area of the lung, or when a partial pneumothorax has been so established as to provide collapse for the upper or, more frequently, the lower part of the lung. It is unsafe to allow the lower part of the lung to remain expanded owing to the dangers following a post-operative aspiration of sputum into the moving lower lobe. In cases of universal affection of the lung a partial and ineffective pneumothorax should be discontinued in favour of a complete thoracoplasty, modified, of course, according to the extent and special localisation of the disease, a slight affection of one lobe indicating a relatively slight resection of the ribs, large cavities, and more serious disease indicating a more radical resection. (2) The performance of the operation in one or more stages will depend on the individual indications afforded by the patient himself, whether or not he is muscular or lean and healthy, or whether or not he appears to be able to tolerate the completion of the operation in one stage. In cases of doubt we consider the two stage operation to be less risky. The technique followed is that recently described by the author in *Tubercle* (1921, ii., No. 9) except that smaller doses of the local anæsthetic, novocaine-adrenalin, are now used followed by a light ether anæsthesia, sufficient to neutralise the pain, but not to abolish the cough reflex. The results in 105 cases have shown that though a greater risk and a smaller result are to be expected from thoracoplasty than from a successful artificial pneumothorax, the former operation results in a great improvement in the prognosis in such cases as are deprived of the effect of the pneumothorax treatment.

4. Cases of insufficient collapse with simple thoracoplasty. It is still to be considered that the fullest possible resection of the ribs through the posterior incision (Sauerbruch's "hook incision") may fail so that the author has now added in these cases resection of the anterior ends of the upper ribs (except the first owing to its inaccessibility), done either at the second stage of the posterior operation or as a separate third stage, and in extreme cases performing an extrapleural apicolysis through the anterior incision, the cavity being plugged with gauze and allowed to heal gradually by granulation and retraction, or with fat, as, in one instance, transplanted from the patient's abdomen. But cases necessitating this procedure are very rare indeed, nor is there such a large field of indication for it as for thoracoplastic resections.

After Dr. Gravesen had read his paper he showed one of his patients, now his most valued nurse in the sanatorium. She was considered to be in a hopeless condition in 1919, but an operation, as described in his paper, was performed in September, 1921, with an excellent result, as the audience were able to see for themselves.

The PRESIDENT considered the two methods of treatment were a great advance, and as a result one could now replace Dante's familiar lines, "All Hope abandon ye who enter here," by "Revive Hope ye who enter here," so far as the treatment of those severe and advanced conditions were concerned.

Mr. J. E. H. ROBERTS (London) did not think it right to assume always that the presence of adhesions is the cause of the bad result obtained by operation. It is quite possible that the results are bad because the type of infection is bad, and that no surgical procedure, under the circumstances, might be successful. One must consider, having regard to the indications for operation, the good-class patients who are able to undergo the prolonged treatment and the poor patients, especially those who afterwards have to return to manual labour. Though adhesions of the "band" type can be divided safely, most types of adhesions cannot be so treated without grave risk. He considered, therefore, that a thoracoplasty must replace the other procedure, though the operation, in his opinion, is still in the experimental stage, and the technique has not been finally established. The class of case chosen for operation, too, is usually the worst, and the results may improve if patients are operated on in an earlier stage. He disliked ether in thoracic cases. Gas and oxygen have all the advantages of the general anæsthetic and none of the disadvantages. The injection of alcohol into the intercostal nerves, when they are reached, reduces shock, paralyses the intercostal muscles, and puts the side affected at rest. After-treatment is of the utmost importance. Mechanical causes may produce afterwards a great, and sometimes serious, increase of the bronchial secretion, when atropine may be of great service. Any tendency to post-operative scoliosis can be prevented by suitable exercises.

Dr. S. VERE PEARSON (Mundesley) emphasised the necessity for these methods of treatment being carried out in a sanatorium, removing the patient from home conditions. It would not be wise to withhold operation because one thinks that adhesions have formed or are going to form, and one should attend to the indications yielded by ordinary physical examination rather than to those yielded by the X rays. He considered that in many cases too long an interval was allowed to elapse between failure to induce an artificial pneumothorax and the performance of a thoracoplasty. Only those having special experience should do the operation. It is not only a capable carpenter who is wanted, but also a capable physician. Nor is an ordinary surgical nursing home suitable for such cases, for the staff lack the necessary experience.

Dr. L. T. BURRELL (London) thought that unilateral cases of disease are more suitable for operative measures, and earlier thoracoplasty might prevent unilateral disease from becoming bilateral. The essential principle is absolute rest before and after treatment. Thoracoplasty is a great advance in treatment, but one should avoid using the word "cure."

Dr. CLAUDE LILLINGSTON (Gorleston-on-Sea) wondered why a small country like Denmark should be so far ahead of us in this matter of the surgical treatment of tuberculosis of the lungs.

Mr. R. TUDOR EDWARDS (London) had done six cases of thoracoplasty, using local anæsthesia under which no real evidence of shock had been observed. He agreed that cases were not got early enough for operation, and, further, in advanced stages of the disease the heart is poisoned and cannot stand the pushing over of the mediastinum which is a necessary part of this operative procedure.

Dr. GRAVESEN, in reply, emphasised the necessity of the expert being expert in everything; the surgeon should also be physician, and the patient should be operated on in the sanatorium where he is under supervision. Answering certain questions and observations arising during the discussion, Dr. Gravesen stated that small effusions in cases of pleurisy sometimes acted beneficially—large effusions acting like a perfect pneumothorax. Scoliosis after a thoracoplasty helps to keep the lung in a collapsed condition, assisting also the circulatory and respiratory balance. He suggested that certain cases of sudden death following the operation might be due to hæmorrhage.

THURSDAY, JULY 26TH.

On the second day, Dr. R. A. YOUNG (London) occupying the chair, Dr. JANE WALKER (London) opened a discussion on the

Social Aspects of Tuberculosis,

with special reference to its infectivity. She said that although tuberculosis is regarded as one of the great killing diseases, being responsible for 10 per cent. of all deaths, it is becoming increasingly clear that the more we know of the disease the more there is to know about it. So far as this country is concerned, the mortality-rate has, however, been falling steadily for the last 150 years and, therefore, cannot be fairly put down to the extra work done and attention paid to it. No doubt the fall is mainly due to causes which have helped to lessen the general mortality-rate, such as the improved standard of living, housing, cleaner clothes, better food, and so forth. But the fall is not constant and is going up in Germany and in Russia, amongst others, and in our own country rose during the war in women, probably as the result of their entering factories in such large numbers, together with the restrictions in food. Too much attention is paid to the seed of the disease, and too little to the soil. Thus the dictum that no big eater ever caught consumption is substantially true and points its obvious moral. For infection to take place contact must be close and prolonged, and the recipient be in a more or less debilitated state. Referring to the recent case—Collins *v.* Hopkins—decided by Mr. Justice McCardie, it is greatly to be regretted that there is no recognised standard, legal or medical, of what constitutes proper disinfection.

Two theories at present hold the field in regard to the spread of the disease: (1) The dose must be massive, intimate, and prolonged; (2) the attack depends on the virulence of the organism. And in both predisposition—i.e., the soil—must not be forgotten. Probably the evidence in favour of the former being the correct view is greater. There is much to be said for the view that, considering the universality of infection, there arises the possibility of a general immunisation of the human organism, as is the case, for example, in scarlet fever; and that the drinking of milk in early childhood containing tubercle bacilli confers immunity. Be that so or not, the clean milk campaign is still one to be encouraged in every way. Tuberculosis is without doubt largely an industrial disease. Treatment in sanatoria has done much good and has cured numbers who otherwise would have been lost to the community, especially amongst the young whose work is still to be done and whose best days are not over. Given to advanced cases it has afforded not only help to the patient but relieved friends and families of anxiety and checked the spread of infection. The value of individual help at the sanatorium in the shape of small talks and advice, the attention paid to a sufficiency of good, wholesome, and yet plain food has been incalculable. Children should have a sufficiently long period of efficient treatment to give them a real chance of acquiring lasting immunity. For the improvement in habits of personal cleanliness, very noticeable in children from the East End, the school medical and nursing services are to be thanked. In general people now live better and certainly drink less. They breathe a less smoke-laden atmosphere and labour-saving devices help to lessen the drudgery of life. We ought to ensure the same good opportunities of treatment to the civilian as to the ex-service man and make satisfactory provision for wife and children while he is away undergoing treatment. Effective after-care machinery is necessary. The question of fitting the patient for particular trades is a difficult one but is being tackled with success at Papworth, Nayland, and other institutions. The establishment of a campaign, comparable to the Framingham Drive in the United States, is an experiment worthy of being applied to this country.

Dr. H. Batty Shaw (London) considered two measures of supreme importance in dealing with tuberculosis: (1) the sterilisation of milk, and (2) segregation of patients, and the removal of children from the source of infection, as there is no evidence that adults, officers of institutions, and so on, take the disease. Segregation of those suffering from tuberculosis is not at all so impracticable a measure as it would seem to be. In any case unless the disease be controlled by the measures indicated all other procedure is useless. The "impure" case of tuberculosis—i.e., tuberculosis in association with other diseases of the lungs—is the dangerous one. Accompanying pneumonia and cavity formation are due to a "mixed infection," and it is impossible to produce these in animals by injection of the tubercle bacillus alone. In a word, tuberculosis of the lungs is really a dual disease, and the term consumption or phthisis should be kept to describe these mixed infections.

Dr. G. B. Dixon (Birmingham) stated that 55 per cent. of children at the age of 5 react to tuberculin and that a survey of 7000 cases in Birmingham gave proof that in a large proportion there were relatives who had either succumbed to the disease or were then suffering from it. Many factors in infection had to be considered. What, for example, are the conditions in infection which at one time will give rise to immunity and at another to serious illness or death? The most vulnerable period of life is the first decade. The measures to be adopted in attempting to control tuberculosis include the protection of the children, reference being made to the Grancher system and the difficulties attendant on its operation, the supervision of known sources of infection, education of the patient and those in association with him, and segregation as far as possible in the patient's own home. Two hundred sleeping shelters are provided to this end in Birmingham. The provision also of a larger number of beds in institutions would be of value, not alone from the nursing point of view, but also economically. Compulsory segregation, however, must be approached with diffidence, though the possession of powers towards this end would form a strong argument in favour of segregation in the patient's own interests.

Dr. J. E. Chapman (London) directed attention to after-care machinery in the struggle against tuberculosis. The occurrence of tuberculosis in a working-class family, particularly if the patient is an adult, is frequently an economic disaster, and care committees, by attending to the economic problem in the cases of individual sufferers and their families, can assist very materially in rendering treatment effective, reducing the risk of relapse and minimising the danger of spread of infection. Unfortunately a variety of circumstances, particularly the war, have retarded the development of these committees. The aim of such a body should be to help the patient to help himself, to give material assistance with the greatest circumspection, and bring him into touch with all local and national agencies which may be able to meet his need. That the committee should have funds at its disposal is desirable but not essential. The unit with which the committee should deal should be the family and not the individual who is suffering from tuberculosis, and, lastly, action should be taken before the circumstances of the family have become disorganised—on the principle that prevention is better than cure.

Dr. C. Muthu (Wells) thought the lack of knowledge with regard to tuberculosis was due to attention being concentrated on the microbe rather than on the man, and the problem is a social, economic, and industrial one. There is a positive correlation between the density of the population and the death-rate from tuberculosis, as was illustrated by figures drawn from London, Glasgow, Dundee, and other crowded centres of population. Thus, also, in India, crowded Bombay presents a higher death-rate than Bangalore, with its garden cities. Among Mahomedan women, secluded in ill-ventilated zenanas, the death-rate is nearly three times as high as amongst men. The more strictly the purdah system is observed the greater the mortality. The experience of the war has shown that when females are subjected to the same influence of occupation the mortality-rate rises as high as, or higher than, the male rate. Tuberculosis is a symptom of poverty, which, with its concomitants of overcrowding and insanitation, undermine the stamina of people so that they fall ready victims to disease. Kaiserling regards tuberculosis as primarily not an infectious disease, but as a disease of nutrition. The soil is more important than the seed, and in India, where tuberculosis amongst cattle is very rarely met with and little or no cow's milk is drunk, nevertheless the disease is very prevalent. Therefore, it is not so much by destroying infection as by attacking social evils, raising the standard of living and thus increasing resistance, that we may hope to eradicate tuberculosis.

Dr. **VERE PEARSON** adverted to the unsatisfactory position in regard to notification which was not fully utilised—e.g., in the examination of contacts and for demographical purposes. Routine measures of disnfection are futile—soap and water, fresh air and sunshine are more important than mere disinfection. Training in the early diagnosis of tuberculosis is mproving though still sadly defective, and there is only one institution in the country devoted to research into the early symptoms of disease, the Clinical Institute at St. Andrews under Sir James Mackenzie.

Dr. **LILLINGSTON** pointed out, with reference to a statement made by another speaker, that though he death-rate in New York from phthisis has allen 50 per cent., that from heart disease has gone up 50 per cent. He suggested that heart disease has, perhaps, become a euphemism for uberculosis.

Dr. A. **NEVILLE COX** (Brighton) asked if spitting is eally a danger. The fact that in Brighton obserration had shown that only a proportion of deaths from tuberculosis amongst children occurred n cases which had been in contact with open nfection at home, argued that the children might well have become infected by playing about in he streets, the only nursery for many of them. Attention was drawn to the possible spread of nfection by dogs and flies. Calling attention to ertain legislative defects, he advocated the extension f the provisions of the Factory Acts to offices, &c., which, under the present conditions, are subject to o supervision.

Dr. J. A. **WATT** (Derby) was satisfied that on the whole the tuberculosis services act efficiently and uickly, though dispensaries, lacking X ray apparatus nd other things, are not by any means properly quipped. So far as care committees were concerned e thought these should be self-contained and he bjected to having to go to other organisations for unds.

Dr. R. **ROBERTSON** (Ventnor) considered that if an nlimited purse were at our disposal tuberculosis would soon be overcome. It should be a matter for he M.O.H. and the tuberculosis officer to evolve an deal method of disinfection.

Dr. G. **FLEMING** (Farnham) pointed out that the all in tuberculosis mortality as manifested by the raphs exhibited, began long before sanatoria and ther similar measures for the treatment of the disease xisted, and wondered, therefore, if the methods arried out in the last 30 years had been of real dvantage in the treatment. Perhaps the advanced ase was much less dangerous from the point of view f infection than the open case in an earlier stage and t work. Money would be spent with greater benefit y concentrating on the treatment of the earlier ages. After all, care committees are only doing hat the State itself should do. The tuberculosis officer hould be trained in general practice as well as in his pecial work and should make it his duty, either ersonally, or by his staff, to investigate the home onditions of every notified case.

Dr. T. E. **WHITE** (Catford) thought that to await he finding of tubercle bacilli in the sputum was o late and desired to know, therefore, when case became notifiable. The doctor in attenance cannot always be held responsible for late otification.

Dr. **MILLER**, speaking as an M.O.H., considered the ifficulty in regard to early notification could be got ver if the general practitioner would only call in the uberculosis officer more frequently.

The **PRESIDENT**, summing up the discussion, eplored the great lack of knowledge regarding the iology of the tubercle bacillus, nor will the disease e stamped out until we learn more concerning the roduction of immunity and the response made by he human subject to infection.

Dr. **JANE WALKER** replying, believed that we should have to come back to Koch's view that there was no danger at all in milk containing bovine tubercle bacilli, while the longer she lived the less she believed in measures of compulsion.

SECTION OF OPHTHALMOLOGY.

THURSDAY, JULY 26TH.

THE morning session was devoted to a discussion on the

Clinical Significance of Scotometry.

Sir **JOHN PARSONS** (London), President of the Section, having, in accordance with precedent, vacated the chair in favour of the Vice-president, Mr. **RANSOM PICKARD** (Exeter), the discussion was opened by Mr. A. H. H. **SINCLAIR** (Edinburgh), who showed an interesting series of charts obtained by Bjerrum's method. He pointed out that scotometry furnished a striking example of the help given in the early diagnosis of disease by the minute study of subjective symptoms. Bjerrum, of Copenhagen, had given us the most delicate and accurate method of estimating areas of relative failure of vision, especially in the more central part of the field. By diminishing the size of the test object used, and at the same time increasing the working distance to 2 metres, his method made it possible to demonstrate small areas of slightly depressed vision, which would otherwise escape notice. A practised and experienced observer could by this method demonstrate upon Bjerrum's screen the course of the large blood-vessels of the retina for some distance from the blind spot. Yet, when familiarity with the method had been gained, it had been found sufficiently rapid for use in out-patient work at Edinburgh. It should be remembered, Mr. Sinclair said, that the blind spot of Mariotte was normally surrounded by an amblyopic zone measuring about 1°; in many cases irregular projections of this zone, above and below, were found normally, which corresponded in position with the points where the large blood-vessels left the disc. One point of importance was the direction of movement of the test object; if moved from the blind to the seeing area, the scotoma would appear larger than if the reverse direction—moving the test object from the seeing area to the blind area—were adopted. It was usual to record the intermediate point between these two observations. A curious phenomenon occasionally observed under certain conditions was that a red object might appear green (its complemental colour) in the peripheral part of the field, but was recognised as red when brought nearer to the fixation point.

In tobacco amblyopia, failure of the light difference sense and paracentral scotoma were constantly present. The scotoma had the following characteristics: bilateral, irregularly oval in shape, extending from the blind spot to the fixation point, which it included, and presenting "areas of greater saturation or density." Debilitating conditions, such as influenza, overwork, diabetes, rendered a patient more susceptible to tobacco amblyopia. If a paracentral scotoma of the type described was met with in a smoker who was a diabetic he should always be advised to stop smoking. Tobacco amblyopia was uncommon in cigarette-smokers, but a chart was shown of a case due to smoking 25 cigarettes daily, with inhalation.

Another chart showed a central scotoma due to cocaine, where the habitual excessive use of cocaine sprayed into the nose had followed its use for some nasal condition. In disseminated sclerosis failure of vision is often an early symptom, and a central scotoma may be present without any contraction of the peripheral field. The most important characteristic of the scotoma in such cases was its tendency to change, to disappear, and reappear.

The early diagnosis of glaucoma had been greatly aided by scotometry. The old saying, "No scotoma, no glaucoma" was true as a general rule, though exceptions did occur. "Bjerrum's symptom," characteristic of glaucoma, might be stated as follows: "The area of normal or most fully preserved vision, as also the area of relative defect, are in contact with the blind spot, or may be said to meet at the blind spot of Mariotte." Or, in other words, "a peripheral area of relative defect can always be traced up to the blind spot provided a sufficiently small test object be employed, and the area of most fully preserved vision is always in contact with, but does not surround the blind spot." (Charts illustrating these points were shown.) In the vast majority of cases of glaucoma relative field changes appear early, and their recognition is of great importance. Mr. Sinclair said that the earliest changes found may be of three types: (1) shrinkage of the 1/2000 field; (2) expansion of the amblyopic zone round the blind spot of Mariotte, which may "break through" to become continuous with a more peripheral defective area; (3) arcuate scotomata, connected with the blind spot, or separate from it. The observer must not be misled by the normal projection of the amblyopic zone, due to the large blood-vessels, already referred to.

Retrobulbar neuritis with central scotoma may result from orbital disease or disease of the accessory nasal sinuses. When the optic nerve is involved, in the optic canal, from disease of the neighbouring sinus, central scotoma is an early symptom. In such a case the scotoma usually affected one eye only, appeared suddenly or developed rapidly, and might be pericentral, or paracentral including the blind spot. The amblyopic zone around the blind spot might be greatly extended. The negative characteristics of the scotoma in these cases were of importance; it had not the areas of saturation characteristic of tobacco, nor the quadrantic formation of a scotoma from a chiasmic lesion. Rhinological and X ray examination were required to locate the lesion of the nerve, which could not be determined from study of the scotoma alone.

Bitemporal hemianopsia occurred in typical form in connexion with tumours of the pituitary body. In some of these cases central vision was affected early, and a quadrantal scotoma could be demonstrated. Such cases tend to run a more rapid course than those in which central vision is not affected till the later stages. Mr. H. M. Traquair had described in detail the course of the development of this quadrantal defect, which was difficult to explain. In conclusion, Mr. Sinclair said that it must be remembered that the valuable evidence afforded by scotometry must always be considered, not by itself, but in association with the evidence from other modes of investigation.

Dr. M. **Gordon Holmes** (London) emphasised the importance of personal factors in this class of work, both in the patient, and still more in the observer. The patient must be made to understand accurately what is required of him and, when once this is done, he should not be questioned during the examination, as his attention will be distracted if this is done. For the same reason all noise, all unnecessary movement, should be avoided. The noise made by most self-registering perimeters was a great objection to their use. More accurate results were obtained by objects moved by the observer's hand. It was important to make friends with your patient, to interest him in what was being done, and to avoid fatiguing his attention. Lastly, "the observer must be careful to maintain an attitude of intellectual honesty"—a difficult matter in a prolonged investigation. To this end it was best not to have before one the result of a former investigation.

Mr. **Malcolm L. Hepburn** (London) showed charts of fields and scotomata in cases of choroidal affections, including under this heading pigmentary degeneration of the retina. For this latter condition, "Raynaud's disease of the choroid" had been suggested as a suitable name. Observation of these cases had led to the conclusion that as long as there was any remainder, even if it were a comparatively small island, in the lower temporal field (usually the last to be lost) the patient would not suffer complete loss of central vision. These patients should be advised never to emigrate to a cold climate.

Mr. H. **Neame** (London) showed a series of charts from a case of pituitary tumour, which illustrated in a striking way the variability of the scotoma—a point recently emphasised in De Schweinitz's Bowman lecture.

Mr. N. **Bishop Harman** (London) called attention to the importance of rapid work. Bjerrum's method made great demands on time and patience. Movement should be from the blind to the seeing area. Speaking of tobacco amblyopia, he gave it as his impression that cases were far less numerous than formerly; also, that it was possible in these cases, by varying the amount of light, to get evidence of depression in the peripheral field.

Sir **John Parsons** emphasised the fact that an amblyopic zone round the blind spot is a perfectly normal phenomenon.

Mr. **Pickard** showed charts of cases presenting unusual features difficult of explanation. The first series were cases of chronic glaucoma where the limitation of the field was concentric, and the blind spot showed little or no enlargement, central vision being normal. His impression was that in these cases the outlook was better than in cases showing marked enlargement of the blind spot. A second series of charts were shown from cases where a similar concentric limitation of the field was due to functional causes; in one of these some enlargement of the blind spot was present. These cases, taken together, illustrated the difficulty that confronts the ophthalmic surgeon in distinguishing between such functional cases and those of early glaucoma with little or no increase of tension. Other charts of atypical cases of glaucoma were shown. Attention was called to the fact that in two of these bacilluria was present. In his experience this was not infrequent, and was, in his opinion, a distinct factor in the causation of glaucoma.

Mr. **Sinclair**, replying on the discussion, said that relative defects in the field were apt to vary from time to time. Given an experienced observer, and an intelligent patient, work with Bjerrum's screen could be done quickly. In regard to tobacco amblyopia, he was of opinion that the peripheral field showed remarkable freedom from restriction.

Exhibition of Cases.

In the afternoon the members of this section visited the Portsmouth Eye and Ear Hospital, where, in addition to other cases of interest, Mr. W. S. **Inman** showed a number of cases illustrating the close connexion between squint and emotional factors. Incidentally it was mentioned that there were no less than 1500 cases of squint among the children of the Portsmouth elementary schools. The cases demonstrated by Mr. Inman were selected as showing the liability of the squint to vary from day to day, and the presence, in their parents or other relatives, of such symptoms as stammering, left-handedness, and alopecia areata. A case was shown in which a transient nystagmus was produced by covering one eye. In other cases squint had either followed or disappeared after a fright or accident. Most of the cases selected for demonstration appeared to be of neurotic temperament. In the informal discussion of these cases it was pointed out that accurate statistical records would be necessary to place beyond doubt any direct causative connexion such as these cases suggested.

Friday, July 27th.

The morning was devoted to a discussion on

Ophthalmology in Relation to the Navy, Army and Air Force.

Sir **John Parsons** took the chair, and special prominence was given to the problems arising in connexion with the Air Force.

Air-Commodore D. **Munro** said they had come to regard inequality of the eyes as dangerous. This was probably also a cause of failure to excel in such games as golf. Most people had "a master eye"; if this was so, it implied that the other eye "lagged behind.'' One eye began by being the better of the two, and the other eye got careless, and neglected. Apart from refraction, a possible explanation was that one eye was better supplied with rods and cones than its fellow, or the visual cortex on one side was better supplied with pyramidal cells than on the other side. Heterophoria, in the Air Force, had come to correlate something more than imperfect muscle balance. It implied bilateral disharmony: the brain was striving to fuse into one two pictures, of which one was better than the other and contained more detail. Their aim was not only to train binocular fusion but also to train the worse eye. "A man with only one eye is, to us, less dangerous than a man with two useful eyes with marked inequality between the two." A one-eyed pilot has his own ways of judging distances, for example, by movements of the head, so as to get an observation from two slightly different angles. Two of the best pilots he knew were practically one-eyed men. To Clements was due the credit of bringing to their notice the importance of orthophoria. Training based on this view had given encouraging results. A striking series of cases of "bad landers" had been improved. In some cases the improvement was so great that the men had later been singled out on account of their special aptitude. The effect of glare in aggravating these defects was of great importance. It led to fatigue of the accommodation, interfering with accommodation and convergence, and aggravating any imbalance of the ocular muscles.

Wing-Comdr. E. C. **CLEMENTS** detailed the steps by which he had arrived at his present conclusions and methods. Before the war he had become interested in a special group of cases, complaining persistently of asthenopia, in spite of repeated changes of glasses. In this group he was impressed by the large proportion of engineers' draughtsmen, men whose work involved frequent use of a sliding rule. Some of these men had automatically got into the habit of closing one eye, finding that they could work better n that way. Later on, in the war, men in the Air Force were sent to him because they could not land properly. When allowed to investigate, he made the startling discovery that about 80 per cent. of all "crashes" at a teaching aerodrome were due to bad andings. An independent investigator estimated the percentage at 70 per cent. On examining these men he was struck with the resemblance to the group of cases first mentioned. All the cases showed evidence of imbalance, and some cases also of suppression. Whereas some six hours in the air, training with an instructor, was found ample for most pilots to enable them to go "solo," many of these "bad-anders" had had about twice as long air training, without reaching such proficiency. "We have to consider a man in the air and not on the ground. It s a totally different problem. From infancy upwards, you have made all your judgments standing on the ground."

In the air unknown quantities complicated the problem. You did not know your distance from the ground. You were a moving object: you were not in contact with the ground. Centrifugal force sometimes complicated matters. For example, in doing a quick "spin" in the air, the eyes tended to be pulled out of their sockets, and, on coming out of the spin, he effect of centrifugal force would take a little time o pass off and allow the ocular muscle balance to ecover itself. It was quite possible for a man to y northwards into a cloud, and to come out of it ying southwards, and head-downwards, without nowing it. To those who did not agree with him s to the importance of heterophoria he would say: "Then let us call this important factor, whatever it is, *x*, and study facts." The clinical fact was that fter the training adopted many bad landers had ecome safe and efficient pilots.

Speaking of the methods of examination followed, he pencil test was used for convergence, bringing it radually nearer till one eye began to wander away: if this happened at a distance of less than two inches, onvergence was considered very good: if beyond four inches, poor; from two to three inches, good. With this test they found three things might happen: one eye might wander out; or both eyes might swing outwards together, or the patient would get a feeling of pain and resistance, and draw back his head. The possession of considerable reserve power of convergence was desirable, whatever the explanation might be. The red-green test was used for measuring deviations. In exophoria and esophoria, 2½° of the one and 1½° of the other were regarded as unsatisfactory. If only one "omnibus" test were available, he would prefer Bishop Harman's movable diaphragm test. In regard to training, the first point was the breaking down of bad habits, and then setting up the good habit. It was no good giving a man an amblyoscope or stereoscope to take home for a week and then to come back and report progress. Daily supervision of these men was necessary, otherwise they were liable to fall into wrong methods in their endeavours to improve. Similar training would in his opinion benefit certain cases in civilian practice.

General Sir W. G. **MACPHERSON** was invited by the President to open the discussion on behalf of the Army, and gave a brief sketch of the way ophthalmic questions had been dealt with, from the old days when it was enough if a recruit could see the bull's-eye on the target at 600 yards up to the present day. In regard to ophthalmology the Army had not gone into it in the same way as the Air Force had done.

Major J. H. **GURLEY**, dealing with visual standards required of recruits, pointed out the waste of money consequent on an unsatisfactory standard; an ill-chosen standard led to numbers of men being discharged from the Army some months after enlistment, on account of inefficient vision, and their period of abortive training cost the country roughly 10s. per day for each man. In his opinion the 1920 standard was the best, leading to the smallest wastage of this kind; it was 6/18 in each eye, capable of improvement to 6/12, 6/6 with glasses. Unfortunately, it had had to be relaxed, as too few men were offering for enlistment.

Mr. **RANSOM PICKARD** referred to the question of night-blindness, and the bearing of hypermetropia and eyestrain on it.

Surg.-Comdr. W. K. D. **BRETON** spoke of the tests employed for gunlayers in the Navy; muscle imbalance of 2° led to rejection. He had refracted under a mydriatic a number of cases of men unable to read 6/4 partly, and found in most of them slight cylindrical defects.

Major M. W. B. **OLIVER** said night-blindness had been one of the commonest causes of malingering in the war, after it had become known that men were discharged on account of it. There was great scope for investigation of this subject with a view to providing some satisfactory test. In the war men had been sent into the front line, who were useless and dangerous to others, if their glasses got lost or broken. Protection of the eyes was a question that would have to be dealt with in the future. Triplex glasses might prevent many cases of injury to the eyes from splinters.

Mr. **BISHOP HARMAN** (London) referring to imbalance, described a personal experience of a hyperphoria of 2° becoming evident in consequence of digestive trouble.

Mr. E. E. **MADDOX** (Bournemouth) emphasised the importance of a sound nervous system in connexion with the cases under discussion; "mental coolness and freedom from mental flutter" were requisite. Abdominal disturbances certainly might influence muscle balance. During an attack of intestinal irritation his own physiological exophoria was changed to esophoria; worms in children produced at times a similar effect; in both instances a severe centripetal impulse was operative. He was in agreement with the figures quoted by Mr. Clements in regard to convergence. The question was not so much whether a man was able to converge his eyes, but of the delicate judgment of the amount of convergence exercised, and the inference from this as to distance. A number of other factors came into play, for instance the apparent expansion of objects in size as you get nearer to them.

Squadron-Leader J. F. CARRUTHERS spoke of the advantage it had been to work with Clements at Hampstead for four months. He had been astonished at the way in which cadets who had crashed over and over again, and broken several aeroplanes, became safe pilots. Facts like that could not be got over however much they might differ on questions of theory. He strongly urged Mr. Clements to publish his unique observations and experiences of the last few years.

Major WRIGHT from his experience in India doubted whether glare was so important a factor as had been stated.

Sir JOHN PARSONS spoke of the complexity of the problem and the extraordinary value of research, as illustrated by Mr. Clements's paper. Once research was begun new problems continually presented themselves. Such a simple question as the relation of visual acuity to musketry had never been adequately investigated. It was a fortunate thing for ophthalmology that the investigations begun in the Air Force in the war had not been stopped by the powers that be. Mr. Clements had touched the crux of the matter when he said that we were accustomed to walk about on land, and flying presented totally different problems. Expensive machines and still more expensive lives were affected by the outcome of these investigations. He differed on some points from Mr. Clements, but the important point was that he had done most valuable work, carried out in a scientific way, and had set an example in regard to these problems that were arising. Splendid work had been done by the Industrial Fatigue Board and by the Institute of Industrial Psychology. The Government could find money and men to carry on these researches which they considered necessary for industry. Money should be available for investigations in the Navy and Army. The proper time for these investigations was in peace-time. When war came, men were asked to give an opinion when they had not always the proper data and material on which to base an opinion. We must emphasise to the Government the need of proper research being done in peace-time on these problems of the naval and military services. Our aim should be the setting up of a definite research department, financed and maintained by the Government.

Commander CLEMENTS, in reply, pointed out our ignorance of the essential nature of the fusion sense. He stated that in the construction of aeroplanes visual conditions had not been studied. Some aeroplanes were "blind-right" and some were "blind-left." A point of interest was that sometimes the red-green test would show esophoria, but, if you fatigued the patient, he would then show exophoria; this must mean that such a patient had a big reserve power and had got into the habit of over-correcting his defect. One remarkable thing in his experience had been the freedom from relapses.

A resolution was proposed by Sir JOHN PARSONS and seconded by Mr. A. C. ROPER (Exeter) recommending the Council of the British Medical Association to press strongly on the Government the great need for research. This was carried unanimously.

Major E. B. SPAETH, U.S. M.C., demonstrated a number of interesting diagrams, photographs, and drawings of plastic operations on the eyelids.

TUBERCULOUS CATTLE AND BLACK PUDDINGS.—Burnley Town Council, on August 29th, passed a resolution instructing their medical officer of health to report as to whether it was customary to allow the blood of tuberculous cattle to be used in the manufacture of black puddings, and what were the dangers of using the blood in this connexion. The Mayor, Dr. J. W. Clegg, said that out of 21,231 animals slaughtered last year only nine were affected and the carcasses destroyed. In the boiling of black puddings a longer time was taken and a greater heat generated than was necessary to kill the germs of tuberculosis. The danger from contamination was practically non-existent.

Reviews and Notices of Books.

A MANUAL OF HISTOLOGY.

By V. H. MOTTRAM, Professor of Physiology in the University of London. London: Methuen and Co. 1923. With 224 figures. Pp. 294. 14*s*.

THIS book is meant to be the companion of the student of physiology while he works through his first elementary course in microscopical anatomy. It should admirably serve its purpose. It is in no sense a book of reference, but it ought to be of real help in enabling the young to get what they so often miss—a sound dependable acquaintance with the commonplace and ordinary elements of the subject. As the author says, his design has been to make a book on histology with diagrams which he could set before a student who asked what to look for under the microscope, and his simple line drawings printed in the text will really help the beginner towards reality better than more elaborate pictures or half-tone reproductions of microphotographs. We may confess that we had not realised that any book could be better calculated to guide first footsteps than Sir Sharpey Schafer's great classic. The difference seems to be that the "Essentials of Histology" is at once an elementary manual of instruction and a book of reference which may be relied on throughout a man's career; Prof. Mottram does not attempt to satisfy the latter requirement, and in consequence makes a better job of the former need. There are a few mistakes: the ratio of red cells to leucocytes in the blood is 500, not 50 (p. 85); malaria does not cause an eosinophilia, and the "mast cells" of the rat's connective tissue are very doubtfully homologous with the "mast cells" of human blood (p. 83).

The only serious criticism which we would make is of the publishers rather than the author. The volume is much too big and clumsy, being printed on thick, soft paper in type unnecessarily large and with considerable margins. It is of the utmost importance that a manual for laboratory use should be easy to carry about; if it is not, the student will leave it in his drawer instead of putting it in his pocket to look at on the way home. Producing a book in a form in which it "would be an ornament to any gentleman's library" may promote the sale of collected editions of standard authors, but it is the last thing that is wanted in books of daily utility. The price of the present volume is, as such things go nowadays, not unreasonable; students of physiology are not so stupid as to pay it any more readily for a large and inconvenient piece of apparatus than for a handy useful companion.

EPIDEMIOLOGY AND PUBLIC HEALTH.

By VICTOR C. VAUGHAN, M.D., LL.D., Emeritus Professor of Hygiene in the University of Michigan. London: Henry Kimpton. 1923. In three volumes. £6 15*s*. Vol. II.

IN this second volume of Prof. Vaughan's work an attempt has been made to group the diseases according to the avenues through which the virus reaches and infects the body; it is, as the author says, only partially successful, as some epidemic diseases have no specific virus and others have multiple avenues of infection. The first group—Nutritional Disorders—includes the definite deficiency diseases, scurvy and beri-beri, and others, the classification of which is still doubtful, such as rickets, pellagra, and goitre. The second group—Alimentary Infections—includes all forms of food poisoning, botulism, the typhoid fevers, cholera, the dysenteries, sprue, Malta fever, and various animal parasitic infections. The third group—Percutaneous Infections—takes in malaria, yellow fever, dengue, tetanus, plague, typhus fever, the relapsing fevers, anthrax, rabies, rat-bite and snake-bite fever, the trypanosomiases, framboesia, the kala-azars, &c. A very full and interesting history of each disease is given, together with the various opinions which have been held at different times as to its ætiology. Many quotations are offered from various authorities on each disease, but unfortunately these quotations are usually undated. This defect may generally be made good by consultation of the bibliography at the end of the chapter, but is rather an important omission in the case of diseases with regard to which views of individuals are changing almost from day to day. For example, McCarrison is credited with the belief that endemic goitre is due to a living organism, and a detailed statement of his argument and an undated quotation are given in support of this belief. It is probable that McCarrison now attributes much more importance to the iodine factor. The chapter on rickets is not as full as some of the others. One of the recommendations for the prevention of rickets—"The child should be kept in the open air with free exposure of the greatest possible extent of its body to the direct action of sunlight for at least three hours a day in order to facilitate the digestion and absorption of food"—suggests a more obliging sun and a better tackled smoke problem than we can boast of in this country. The chapters on malaria and yellow fever are, as was to be expected, especially interesting.

This work is a careful and painstaking effort to bring our knowledge of these diseases up to date, and we can cordially recommend it as a useful book of reference and a valuable addition to the library of any medical man.

SOCIAL MEDICINE.

Les médicins sociologues et hommes d'état. By P. TRISCA. Paris: Felix Alcan. 1923. Pp. 224. Fr. 10.

THE gist of this interesting little book is that the evils from which the world is suffering might be greatly lessened if medical men set themselves to impress upon governments that the crying need is for public health in the widest sense—not only the prevention of zymotic diseases, but the regulation or abolition of drunkenness, syphilis, and tuberculosis, together with provision for healthy housing. Dr. Trisca sets a high standard for medical men—they should be strict abstainers and should never smoke; the end of the medical profession should not be money-making. This may be ideal, but yet medical men must live, and Dr. Trisca does not clearly explain how it is to be brought about. The first portion of the book is mainly taken up with short biographies of various medical men in different countries who have interested themselves in social matters or who have sat in Parliament, and the author casts his net wide, for he includes Darwin, Locke, Rabelais, and Quesnay.

We wonder a little that he has not mentioned Renaudot, who in 1631 started the first French newspaper, the *Gazette de France*. Renaudot practised in Paris and was the originator of the Monts-de-Piété, where the poor could obtain small loans on small security, and also of intelligence offices where they could obtain advice on medical and allied matters.

Though Dr. Trisca's maxims are counsels of perfection, he has certainly set an ideal which it would be well to follow.

LOEB CLASSICAL LIBRARY.

Hippocrates. Vol. I. With an English Translation by W. H. S. JONES. London: Heinemann. 1923. Pp. 362. 10*s*.

THIS volume contains the following Hippocratic treatises: Ancient Medicine; Airs, Waters, Places; Epidemics I. and III.; The Oath; Precepts; Nutriment. The selection, says the translator, "is intended to be typical of the whole Hippocratic *Corpus;* in it are included works belonging to the chief classes of which the collection is composed." Of these, the two last, though included in the Corpus, are almost certainly not genuine works of Hippocrates—i.e., of the author of Aphorisms, Epidemics I. and III. and of Airs, Waters, Places. In addition to his translation Mr. Jones supplies a most interesting introduction dealing with the Hippocratic collection in general and with the meanings of various medical terms. There is also a separate introduction to each individual treatise and in particular that to Airs, Waters, Places gives a clear account of the meaning of the terms heliacal, cosmical, and acronycal, as applied to the rising and setting of stars or groups of stars for the purpose of identifying the beginnings and ends of the seasons. We are glad to find this explanation, for many editions of the classics never give it—for instance, hardly any school edition of the Georgics does. An honourable exception to the general neglect is Prof. A. W. Mair's translation of Hesiod. Unless the reader is acquainted with the technical meanings of the terms "rising" and "setting" a passage such as this from Airs, Waters, Places XI. is meaningless: "One must also guard against the risings of the stars, especially of the Dog Star, then of Arcturus, and also of the setting of the Pleiades."

It is no doubt difficult for a busy medical man to find time to read Hippocrates, but if he should be able to do so, he will find no better translation than the volume before us. We look with interest to the coming of the remaining volumes.

BUGS.

A Biology of the British Hemiptera-Heteroptera. By EDWARD A. BUTLER, B.A., B.Sc., F.E.S. London: H. F. and G. Witherby. 1923. Pp. viii. and 682. £3 3*s*.

THIS handsome volume contains a very full account of the life-histories, so far as they are known, of the species of the suborder of Hemiptera-Heteroptera, or typical bugs, that are found in Britain, and in each case the life-history includes, as far as possible, not only the manner of life and the distribution and seasonal prevalence of the adult, but also corresponding particulars of the larval stages, and necessary details regarding the egg.

In excluding taxonomy and generic and specific diagnoses the author has impaired the usefulness of his work. His statement that the beak of bugs is used as a piercing organ is too general; the beak is not so used by the bed-bug, but is arched backwards to give exclusive play to the slender suctorial tube formed by the mandibles and maxillæ. In his account of the organs of Berlese and Ribaga—those curious structures peculiar, so far as is known, to females of the bed-bug—he has unfortunately overlooked the extraordinarily interesting work of Major F. W. Cragg—work full of suggestion equally to the biologist, the physiologist, and the pathologist. Cragg has shown that these organs, though distant from the genital apparatus and not possessing any obvious ducts, receive the exuberant spermatozoa from the male and filter them into the body cavity of the female insect; that the spermatozoa pass from the body cavity into the spermathecal chambers through the walls of the latter, and that they pass on to the ovaries not in the lumen of the oviduct but in the substance of its wall. Apparently only a small number of the spermatozoa reach the ovary, and the great mass of them are destined for some work other than fertilisation of ova. The author merely repeats Berlese's opinion that the organ bearing his name appears to ingest and destroy the excess of spermatozoa, although the evidence of Cragg's observations was published, in 1920, in the *Indian Journal of Medical Research*, and was demonstrated in London in 1922.

The book is a useful introduction, though without any such express intention, to a group of insects that is full of interest to the medical profession. For the facts that the bed-bug is a potential agent for the transmission of disease to man, and indeed in the case of kala-azar is reasonably suspected of operating effectively in such transmission, and that certain reduviid bugs are demonstrated intermediaries in the propagation of Chagas's trypanosomiasis in South America, bring the suborder definitely within the domain of medicine. The facts, again, that several species of bugs are copiously infected with flagellate protozoa akin to certain common and disastrous blood parasites of man in tropical countries, and that some of these bugs are known to owe their infection to plants, like spurges and dog-banes, that have a milky sap, invest this suborder with an interest which, though at present predominantly speculative, is seriously attractive to the pathologist. Furthermore, to the student of parasitology a group of insects that provides such an easy supply of flagellate protozoa for experimental work should be particularly alluring.

Early Diagnosis of the Acute Abdomen.

Second edition. By Zachary Cope, B.A., M.D., M.S. Lond., F.R.C.S. Eng., Surgeon to Out-patients, St. Mary's Hospital, Paddington; Senior Surgeon to the Bolingbroke Hospital, Wandsworth Common; late Hunterian Professor, Royal College of Surgeons. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 223. 12*s.* 6*d.*

In this second edition of a valuable little work few changes have been made, but they considerably enhance its practical usefulness. The general arrangement of the work is unaltered. It is of interest to note that the author lays stress upon a fact which is often overlooked—namely, that free fluid within the peritoneal cavity may be simulated by dilated coils of intestine which will not only give dullness in the flanks but a dullness which shifts with the position of the patient. Important changes have been made in the description of the areas of superficial tenderness which may be met with in cases of appendicitis, and the author's account is now more in conformity with that usually given. The method of estimating the area of hyperæsthesia by means of a dragged pin is now advocated in preference to pinching a fold of skin. The area in which such hyperæsthesia is found is one lying parallel to the right Poupart's ligament and just above it and is dependent upon the distension of the viscus. Sufficient stress is hardly laid upon the fact that the sudden disappearance of this area of hyperæsthesia is one of the earliest signs of perforation of the appendix. Although attention is directed to the importance of early diagnosis of perforated gastric or duodenal ulcer that group of cases in which the onset is gradual and where the patient may walk up for advice is not given much prominence. In such cases the pulse may be only 60 and the patient may show no signs of primary shock, although there is already much rigidity of the rectus.

The book is an extremely valuable guide to all holding positions as house surgeon or who have recently entered general practice. As such it has evidently enjoyed a popularity which the present edition will increase.

Blood and Blood Diseases.

Blutkrankheiten und Blutdiagnostik. Von Dr. Med. Otto Naegeli, Professor der Inneren Medizin an der Universität Zürich. Vierte Auflage. Berlin: Julius Springer. 1923. With 25 coloured plates. Pp. 587. £1 5*s.*

Prof. Naegeli's book requires no introduction to hæmatologists in this country; since the appearance of the first edition it has remained one of the most useful works of reference extant on blood and blood diseases, and this, the fourth edition, will serve to confirm it in its place. Notice has been taken of most recent work of importance on the subject, and several new sections and many illustrations have been added.

Of the new matter contained in this edition some of the most interesting is that in the section on the Hæmorrhagic Diathesis, under which head the author groups together all conditions in which purpuric manifestations play a part; this results in bringing some very diverse conditions into juxtaposition, and since a few glimmerings of light have of late years been thrown on some of the underlying causes of the various conditions described, it is questionable if this arrangement is now quite justifiable. It is not conducive to any true understanding of the matter to find Goldmann's Hereditary Hæmorrhagic Telangiectases standing at the head of a list which includes also Avitamosis, Anaphylaxis, and Hæmophilia. In this section, however, Prof. Naegeli does good service in calling attention to the importance of the blood platelets in purpuric conditions; in those associated with a withdrawal of these bodies he makes a sharp distinction between "benign" or idiopathic forms and those secondary to an infective process which he calls "malignant"; to the former he would apparently limit the term "Werlhof's disease"; the latter he regards as examples of the "aleukia" of Frank. The blood platelets in fact receive throughout a consideration from Prof. Naegeli in pleasing contrast to their treatment by many authors in this country. The choice of the dry-slide method of Fonio for counting them, however, was not fortunate; whatever may be said as to the relative accuracy of the methods, the wet method is far easier to carry out. The 25 plates in colour at the end of the book are a valuable feature; their subjects are happily chosen; the original drawings by R. Sarno of Naples were evidently well done and their reproduction is pleasing. The book contains a voluminous and useful bibliography.

The Periodontal Tissues.

Lectures on the Diseases of the Periodontal Tissues due to Infection in their Relation to Toxæmia. By J. H. Mummery, J. G. Turner, Sir William Willcox, and Prof. E. E. Glynn. London: Dental Board of the United Kingdom. 1923. Pp. 96. 2*s.* 6*d.*

The Dental Board has done well to publish the four lectures on periodontal disease which were delivered at various centres during the earlier part of the year. They contain matter of great interest, much of which does not find any place in the various text-books. There is a special significance attaching to the appearance of this book, for it represents the beginning of post-registration teaching carried out as a part of the duties of the official body which controls the dental profession. Though this book does not pretend to be a complete manual on pyorrhœa, yet within a space of less than 100 pages it covers a very wide field. The patho-histology is dealt with by Mr. Mummery in a comprehensive manner. Mr. Turner contributes the lecture on the local clinical symptoms, which in the extent and accuracy of its observations could hardly be bettered. The systemic effects are discussed by Sir William Willcox on the lines made familiar by previous contributions from this writer. The bacteriology of pyorrhœa is dealt with by Prof. Glynn. Of all aspects of pyorrhœa this is, perhaps, the most confusing. Though Prof. Glynn cannot assign any specific organism to this disease his chapter is a masterly review of the subject. It is no disparagement to the other writers to say that this chapter is the most notable feature of the book, which would be well worth buying on its account alone.

Since pyorrhœa plays a not unimportant part in general medicine, this volume may be commended to both medical and dental practitioners as a sound and comprehensive review of the present state of our knowledge of pyorrhœa.

The Secret Journal of Charles Dunbar.

By J. Maconechy. Collins. Vi. + 276 pp. 7*s.* 6*d.*

An instance of hereditary ability marks the authorship of this recently issued novel. It depicts the life of a country parson and his conscientious endeavours to perform the duties of his profession, though realising the limitations of his religious convictions and belief; a position which appeals to many outside the clerical circle, and in particular to men of science. The book relies upon the study of character, rather than plot, for its interest, and should recommend itself to the medical profession as the work of a direct descendant of the sister of William and John Hunter.

IN this little corner drug store in Colorado 30 years ago, Antiphlogistine was first compounded.

Brought forward by physicians as sponsors and introduced exclusively through the medical press, Antiphlogistine met a real need in the practice of medicine which sufficiently accounts for the cordial reception given the new therapeutic agent and the steady extension of its circle of friends.

In a remarkably short time, its use spread from Coast to Coast, and brought its sponsors face to face with problems of production and distribution which called for constant adjustment. These problems have been solved and always without affecting in the slightest degree the original spirit of the enterprise—to provide the practitioner with the best non-toxic antiseptic and osmotic application for the treatment of inflammation and congestion.

Today, Antiphlogistine is available anywhere on the globe and its condition and therapeutic qualities are absolutely uniform wherever it is found. The support given it by the medical profession and the medical press everywhere have made it the most extensively employed medical preparation in the world. No trouble has been spared either as regards equipment or personnel to insure the maintenance of proper standards in manufacture, and from whatever outpost the demand may call in the future, the service will follow.

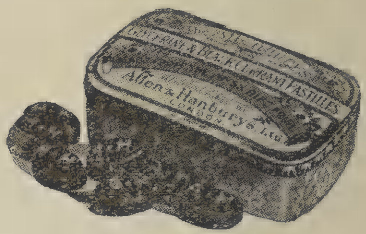
THE

'Allenburys' Throat Pastilles

Glycerine & Black Currant Pastilles

Delicate in flavour. Efficient in use.

They are manufactured from pure glycerine and the fresh juice of choice ripe black currants by a special process which conserves the full value and flavour of the fruit. The 'Allenburys' Glycerine and Black Currant Pastilles have a demulcent and mildly astringent effect, most useful in allaying simple irritations of the throat. They dissolve slowly and uniformly, and have a delicious and slightly acidulous flavour.



Supplied in metal boxes containing 2 ozs., 4 ozs., 8 ozs. and 1 lb. respectively.

The 'Allenburys' Medicated Pastilles

may be relied upon to present the accurate amounts of the active ingredients and to be thoroughly effective in use. They dissolve slowly and uniformly, ensuring a thorough suffusion of the medicament over the mucous membrane. 81 varieties of the 'Allenburys' Medicated Pastilles are manufactured.

Packed in original tin boxes containing 3 ozs., 8 ozs. and 1 lb. respectively.

Descriptive Booklet and Price List sent on request to members of the Medical Profession.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 8, 1923.

THE EARTHQUAKE IN JAPAN.

THE appalling disaster which befell the middle island of Japan last Saturday has evoked the active sympathy of the civilised world. The disaster was not without precedent or altogether unexpected. There is a yearly average of 96 perceptible shocks in Tokio, and every Japanese boy or girl is brought up to expect one severe earthquake in his or her lifetime. It was after the last severe quake in Tokio that the seismographic station was opened which has added so much to our knowledge of movements in the earth's crust, but shock followed shock so rapidly on Saturday that the instruments can only have recorded their own destruction. Position on a low seaboard still further imperils Japanese cities, situated, as they already are, on a direct line of stress, the result of a specially sharp fold in the earth's crust; for, just as in Calabria, at San Francisco, and on the Mexican seaboard, shock was followed by fire, and fire by tidal wave. The great Indian earthquake of 1897 which crossed a continent would have produced fearful devastation had not the country traversed been wild and sparsely populated. We may trust that the high level of civilisation was sufficient to prevent the mad orgy of riot and rapine which has followed on such catastrophes under less favourable circumstances, for the rapid development of Japanese culture has hardly been less astonishing than the local changes in the earth's crust which caused the disaster. Immunity from considerable vibration during recent years had made experts apprehensive that seismic disturbance, when it should reappear, might be of special severity.

The Eastern island empire stands in special relation medically to our own, for it is one of the two countries, Italy being the other, with which complete medical reciprocity has been established, and reference to the foreign section of the Medical Register shows the extent to which advantage has been taken of this mutual concession. During the last few years a number of important scientific announcements have originated from Japanese universities, which are both numerous and well equipped; reminder is scarcely needed in regard to the pioneer work on experimental tar cancer of YAMAGIWA, ICHIKAWA, and TSUTSUI, and the discovery, after much painstaking research, of the spirochæte of infectious jaundice, associated with the names of INADA, IDO, HOKI, KANEKO, and ITO. We have received only this week the first imposing volume of a series of scientific reports from the Government Institute for Infectious Diseases at the Tokio Imperial University, of which Prof. MATARO NAGAYO is director. This work, which has already appeared in the *Japanese Journal of Experimental Medicine*, is now made accessible for the common stock of medical knowledge by the decision of the Institute to publish an account of all research in some European language; and a large part of this admirably printed and illustrated volume is in English. We have yet to learn whether the disaster will be a serious setback to scientific work in Tokio, nor do we yet know to what extent the scientific workers have perished with their universities and institutes, but the motto of those who survive will, we feel sure, be that of Italy after the Calabrian disaster, when Sign. MARCORA quoted, amidst the applause of the Italian deputies, the words "Post fata resurgo." In the present case, should rehabilitation be required, medical and scientific friends in this country will gladly render any aid at their disposal.

◆

PASTEURISED MILK.

THE prime importance of milk as a food has been emphasised of late by the exponents of what is known as the "newer nutrition," while medical officers of health, on the other hand, have not ceased to put prominently before the public the dangers of a contaminated milk-supply. It is not surprising, therefore, that discussions as to the best policy to adopt for the purpose of obtaining a safe milk-supply have occupied a large part of the time of recent sanitary congresses. At the National Milk Conference held at the Guildhall last year there were doughty protagonists of clean raw milk from tuberculin-tested herds and of adequately pasteurised milk, while perhaps the surprise of the conference was the general endorsement by leading medical authorities of the value of a third form of safe milk, which did not appear on the programme—namely, dried milk. The National Clean Milk Society has convened a further conference at the Guildhall in November next to consider pasteurisation. The appearance is therefore opportune of a report on the Pasteurisation of Milk by Dr. J. M. HAMILL, a medical officer of the Ministry of Health. This report, of which a summary was given in THE LANCET of August 18th (p. 338), puts the case clearly and reasonably for pasteurisation as defined by the new regulations—that is to say, milk which has been exposed once for 30 minutes to a temperature between 145–150° F. (63–66° C.). Milk so treated is rendered reasonably safe as regards the risk of transmitting disease; the pathogenic organisms liable to be found in milk are, with the exception of the tubercle bacillus, killed by the process, and that organism, if not killed, appears to be so attenuated as to become harmless. This appears from the results of an important and laborious investigation by Dr. F. W. CAMPBELL BROWN, printed in the same issue, which may be regarded as settling once for all the thermal death-point of the tubercle bacillus in milk. The difficulty of striking the happy point where sterilisation is sufficient and heat deterioration has not set in is also manifest in the report on condensed milk, which is summarised in another column. In many cases a few spores remain without doing harm.

The effect of pasteurisation on the chemical and physical characters of milk must also be considered. Taste and flavour are scarcely altered. At 145° F. (62·8° C.) the separation of cream is affected but little; at 148° F. (64·4° C.), however, the cream line may be decreased by 40 per cent. This in itself is unimportant; in fact, one of the advantages of homogenised milk is that the cream will not separate. At 145° F. (62·8° C.) the milk proteins are unaltered, but at 150° F. (65·6° C.) 5 per cent. of the albumin is coagulated. There is no evidence that coagulated albumin in pasteurised or dried milk is more difficult to digest, just as there is no reason to suppose that the white of a raw egg is more digestible than the white of a boiled egg. The enzymes are slightly affected, but we do not know if that is a drawback. Junket can be made more easily from pasteurised milk. The soluble calcium and magnesium phosphate are not precipitated. Vitamins A and B are probably not affected; vitamin C is partially destroyed. As the destruction of vitamin C is due to heat and oxidation combined, precautions to exclude air during the process are beneficial. These matters are still under investigation. Transport is still an unsolved problem; distribution even of clean tubercle-free milk gives opportunities for contamination with pathogenic organisms, but if milk is to reach everyone it must often travel long distances and be transportable. Pasteurisation helps to bring this valuable food within reach of town dwellers with its taste, flavour, and nutritive value practically unimpaired. After pasteurisation—and this cannot be too strongly insisted upon—it must be as carefully handled as clean raw milk. Dirty or stale milk if pasteurised will give a higher bacterial count than fresh clean milk pasteurised; nor will it even pay to pasteurise stale milk, as the flavour is not improved thereby.

Pasteurised milk agrees with children as well as raw milk, and the partial loss of vitamin C, whatever it may amount to, can readily be made good by giving orange or other fruit juice. The physical and chemical alterations resulting from pasteurisation are held by some to indicate the possibility of other nutritive changes of which we do not know and which may be important; such hypothetical considerations cannot be allowed to outweigh the important positive advantages accruing from pasteurisation. It seems to be peculiarly difficult to avoid prejudice in this matter of the heat treatment of milk. More than other European countries we have been accustomed to drink our milk raw—east of the Balkans uncurdled milk is not regarded as fit for human food—and the opponents of pasteurisation call in Nature as their witness. Cow's milk, however, is no more a natural food for man than is a hen's egg. Romulus and Remus obtained an unnatural food in a natural manner, sterile and at blood heat. We have to content ourselves with an unnatural food obtained in an unnatural manner and must call in science, not Nature, to our aid. The British farmer is even more afraid of science than the British manufacturer, and it would be a difficult feat for the scientific advisers of the Ministry of Agriculture to persuade the farmers of our western counties to adopt the practice of pasteurisation. The very word stinks of science. It so happens, however, that in these western counties it has been the practice for years to pasteurise such milk as is made into clotted cream or butter and to drink the "scald" milk, without anyone worrying as to whether the nutritive value of the cream, butter, or scald milk were thereby impaired. The old-fashioned Devonshire farmer would, in fact, regard his method of preparing cream and making butter as a "natural" process in strong contrast to the unholy scientific operations of the separator. We need to get rid of prejudice and patiently to apply our knowledge to make available for urbanised populations this valuable food which the forethought of our ancestors has gained for us.

PATHOLOGICAL DEPARTMENTS.

We received lately a copy of the annual report of the pathological department of the University of Leeds which continues its prosperous career under Prof. M. J. Stewart. The staffing of the department has been much improved by the appointment of Dr. J. W. McLeod as first occupant of the chair of bacteriology, due to the munificence of Sir Edward Brotherton, and a considerable step in progress has been taken by the institution of a course in general bacteriology for science and technical students similar to that started in Manchester by Prof. W. W. C. Topley. In this two of the liveliest of our modern universities are leading a substantial and much-needed reform of the state in which bacteriology was a wholly medical subject. But the appointment of Prof. McLeod as city bacteriologist raises other considerations. The diagnostic work of the department in 1922 involved the examination of nearly 18,000 specimens, of which only some 5000 (less than 30 per cent.) came from the General Infirmary, the balance representing public health material, especially from venereal diseases clinics, sent by various bodies, mostly the city of Leeds. The excuse for this utilisation of a department of a university, whose business is teaching and the advancement of learning, is doubtless to be found in the accounts, which show that 41 per cent. of the income of the department is derived from fees for diagnostic work. How far this diversion of the university's activities into money-making channels extends, we do not know, but it is fairly safe to assume that, for example, the department of mathematics is not called upon to earn money by doing actuarial work for insurance companies and commercial firms. But as far as pathological departments are concerned, the practice is unfortunately widely spread through the country. In weakening the ideals of higher education the effect is bad enough. It is also much to be deplored from the point of view of effective and progressive public health administration. The larger hospitals and medical schools have long since realised that they cannot hope to get the best—or, indeed, anything approaching the best—out of laboratory diagnosis unless they have their own laboratories in intimate contact, topographical and personal, with the clinical staff and the patients from whom the materials are derived; sending things down the road and having answers back on pieces of paper is by comparison no use at all. Similarly in public health work the city bacteriologist should be one of the right hands of the medical officer of health, and in continuous and immediate communication with him. Only in this way, we feel sure, can diagnostic bacteriology make its proper contribution to public health administration, and it is surprising that great and enterprising municipalities such as Leeds are content—if they really are content—to go on with a method so imperfect and makeshift. And when they have bacteriological laboratories of their own, professors of pathology will have no need to hold meetings, as described in the Leeds report, to chaffer with the Ministry of Health about the price they are prepared to accept for Wassermanns. As to Manchester the trenchant words of Dr. C. Powell White in our correspondence columns reflect the views at any rate of one section of pathologists on the need for a status independent of outside work.

THE RAPPROCHEMENT OF HOSPITALS AND CONTRIBUTORS.

The year 1922 will be remembered as a year of depression, unemployment, and trade shortage in Sheffield as elsewhere; yet, for the first time for many years, the income of the local voluntary hospitals balanced their expenditure, and the accumulated debt due to the bank was reduced from £116,000 to £87,132. This happy result was achieved mainly by the efforts of the Sheffield Joint Hospitals Council, whose first annual report is of more than local interest. It takes the form of an attractive book of 72 pages, of which tabulated statistics occupy only three, further information being presented with running comment. The right sort of notoriety has evidently been achieved—that which not only stimulates the interest of contributors in their hospitals but also brings them into touch with each other as a corporate body with a common aim. The secretary of the Council has met representatives of some 50 local societies and associations, and during the year there has been formed the Sheffield and District Association of Hospital Contributors, which has rendered valuable service in promoting the growth of the " 1*d.* in the £ " contributory scheme of employers and employees.

This scheme, which is described in a separate " Contributor's Handbook," is essentially an agreement to give, either by means of deductions from wages or directly, a penny for every pound of wages earned weekly to the Joint Hospitals Council. In return for such contributions free treatment and free maintenance is available on admission to any one of the five Sheffield hospitals, though contributors able to pay nursing home fees are requested not to avail themselves of these facilities. The success of the enterprise can hardly lie in this simple appeal alone, but is obviously due to the skill with which it has been organised, and the sympathy shown to the natural desire of the contributor, whether an individual or a firm, to receive some little recognition of his effort to support the hospital and some responsibility for its further maintenance. Such is afforded not only by the opportunity given to Works Hospital Committees to send delegates to the Association of Hospital Contributors, which in turn is adequately represented on the Joint Hospitals Council, but by the classified lists of contributing firms and individual contributors which form the largest part of the first annual report of the Council. The classifications are twofold—geographical, and according to trades—and friendly rivalry may thus be stimulated in at least two directions. Finally, a periodical news-sheet, in poster form, is published. The August issue gives notice of the next quarterly meeting of delegates, announces the programme of a series of free health lectures for the winter session, reports the advent of a new motor ambulance, and gives other information calculated to interest the contributing public.

We have set out the Sheffield plan in some detail because it is obvious that by this or similar means adopted in other industrial areas the voluntary hospital system can be saved. The days, however, when the hospitals could afford to stand detached and coldly solicit help by publication of figures showing huge deficits are gone. A more intimate relation between contributor and hospital boards has come to stay. Criticisms will arise, will be resented, and perhaps quashed, will be repeated, and—dare we say it—improvements in administration will ultimately result. Attention was recently called in our columns [1] to rigid rules in certain hospitals throughout the country limiting the use of the telephone, forbidding the introduction of fruit under any circumstances into the wards, and so forth ; the quality and monotony of the full diet allowed to convalescents might also have been mentioned. It may well be that Associations of Hospital Contributors organised on the lines of the Sheffield and District Association will in the future find important work falling to their hands.

---

Annotations.

"Ne quid nimis."

THE PREVENTION OF SIMPLE GOITRE.

THYROID enlargement is not the serious problem in this country that it is in Switzerland and some of the American States. This fact lends special interest to the account of an outbreak of acute goitre in a Lancashire children's home, recorded in our present issue. Dr. E. W. Adams and Dr. H. N. Crossley are not prepared to state whether goitre is or is not unduly prevalent around Rochdale, but they have no doubt that a high degree of thyroid instability is present among the children of the cottage homes in this area. It is hoped that further investigation may throw light on a very puzzling outbreak. It is endemic rather than epidemic goitre that has received most attention in recent times. In America an exhaustive study of the physiology and pathology of the thyroid gland, extending over some ten years, by Dr. David Marine and his collaborators, Drs. C. H. Lenhart, O. P. Kimball, and J. M. Rogoff,[1] has resulted in the development of a prophylactic scheme which deserves careful attention. Not long ago [2] we had occasion to discuss iodine prophylaxis with special reference to the problem in Switzerland, and concluded that the introduction of a small percentage of potassium iodide to the common salt in daily use would be a cheap and useful method. Although the ultimate cause of goitre is totally unknown, its immediate cause is claimed to lie in a lack of iodine, and the American authors support the view which is gaining ground that thyroid hyperplasia is a compensatory reaction arising in the course of a metabolic disturbance and immediately depending on a relative or an absolute deficiency of iodine. The prevention of human goitre on a large scale was begun in Cleveland in 1917, and the method adopted was the administration of 2 g. of sodium iodide in 0·2 g. doses daily for ten consecutive school days distributed over a period of two weeks and repeated each autumn and spring. This amount of iodine is admitted to be excessive, and beyond the ability of the thyroid to utilise and store. One gramme distributed over a longer period would be better ; indeed, 3 to 5 mg. of iodine twice weekly over a period of a month, and repeated twice yearly, would amply suffice. Dr. R. Klinger, of Zurich, instead of sodium iodide, employs an organic iodide which is non-hygroscopic, very stable, practically tasteless—a vegetable fatty acid compound which is combined with chocolate and made into tablets, each containing 5 mg. of iodine. This method has been employed in all the schools in the cantons of St. Gallen, Berne, and Zurich with most striking results—e.g., incidence of goitre among all the school children in the Canton of St. Gallen : January, 1919, 87·6 per cent. ; January, 1922, 13·1 per cent. The possibility of harm from a very small dosage used by the authors is negligible. A mild rash occurred in but 1 per 1000 of the cases treated, and in Switzerland not a single case of rash has been seen, nor has a case of exophthalmic goitre been produced. It comes to this—that if in endemic goitre districts every woman would keep her thyroid saturated with iodine during every pregnancy, she would not develop goitre, nor would there be any tendency toward goitre formation in the thyroid of the child. If every girl would keep her thyroid saturated with iodine during adolescence, that is from the age of 11 to 16 inclusive, none would develop goitre. A large majority of the goitres in boys are congenital, and could be prevented by the administration of iodine to the mother during pregnancy. In young individuals with thyroid enlargement of recent development the curative effects of iodine are very striking, and amount to complete relief. In long-standing goitre neither iodine nor desiccated thyroid are of much value in relieving the deformity. Thus prophylactic treatment is obviously the thing to aim at. As is pointed out in the *Bulletin*, the prevention of goitre is good preventive medicine; it is better preventive surgery.

PSYCHOPATHOLOGY AND THE PRACTITIONER.

In the *Clinical Journal* of August 22nd Dr. W. H. Maxwell Telling, writing from the standpoint of a consulting physician, discusses the bearing of modern psychology on general practice. After outlining the theories of psychopathology and the scope of its clinical application, he leads up to the striking enunciation that it is the greatest remedial advance of modern medicine; from this arise some important questions. Though others may share in the preventive and educational applications of modern psychology, yet with us should rest its use in curative medicine. But he makes note—though the note is now losing its novelty—that nearly every practitioner faces the public totally unequipped in this most vital branch of medicine, and, as a correlated evil, that one sees young practitioners with an entirely insufficient post-graduate training in ordinary clinical medicine taking up psychopathology and mindful of little else. Dr. Telling's enumeration of the physical symptoms of disease which may have entirely or mainly psychical causes is, as he says, almost beyond credibility till one studies them from the new angle. His practical conclusion is that it does not follow that the treatment of all these cases can be carried out best in general practice, but they can there be sorted out and sent to the real source of cure rather than to the operating theatre, or the electrician, or allowed to drift to the "Christian Scientist" or the quack. The article is a forceful argument for regularising the position of psychopathology so as to ensure that the practitioner shall be enabled to recognise his cases and know which are within his powers of treatment and which are beyond, and, in the other direction, that the would-be psychopathologist shall go through the mill like other aspirants to the ranks of specialism.

SYPHILIS OF THE UTERUS AND ADNEXA.

Dr. Bernard Portis, of the Nelson Morris Memorial Institute for Medical Research, remarks[1] that syphilis of the uterus is a comparatively rare affection, apart from the primary lesion on the cervix, which is the commonest type of syphilitic involvement of the female internal reproductive organs. The frequency of cervical chancres varies according to different observers from 1·5 per cent. (Gellhorn and Ehrenfest) to 8 per cent. (Oppenheim), and 10 per cent. (Ozenne) of all primary lesions of the female genitalia. The paucity of symptoms and rapid repair without scar formation, as well as the fact that comparatively few examinations of the cervix are made in the early stages of syphilis, account for the discrepancy in these figures. According to Ozenne, the anterior lip is involved twice as frequently as the posterior, and in about half the cases both lips are affected. Multiple lesions have often been observed. The cervical chancre may assume either an erosive form or much less frequently an ulcerative form simulating carcinoma. Frank has shown that in the pregnant uterus the lesions may persist up to a period of five months and produce very extensive induration, which may prevent spontaneous delivery of the child. Secondary lesions of the cervix have been divided by Ozenne into erythematous, erosive, hypertrophic, papular, and ulcerative forms, of which the papular is the most frequent. Tertiary lesions of the cervix may assume a gummatous type, in which a diffuse infiltration involves the entire cervix, or a sclerotic type, which may develop on pre-existing primary, secondary, or tertiary lesions. The features common to all syphilitic lesions of the cervix are stated by Gellhorn and Ehrenfest to be as follows: (1) There is little secretion except in the tertiary ulcers or necrotic gummata; (2) there is little pain either spontaneously or resulting from direct trauma; (3) the lesions occur some distance from the external os, which is rarely the case in non-specific ulcers of the cervix; (4) the ulcers are usually covered with a film-like deposit which may be wiped off easily and exhibit a fatty lustre; (5) there is very little, if any, inflammatory reaction. In most of the reported cases of syphilis of the body of the uterus the evidence of the syphilitic nature of the process is inadequate. Primary and secondary syphilis of the body of the uterus has been rarely observed, probably owing to the fact that *Trep. pallidum* shows a predilection for squamous epithelium. Two main types of tertiary syphilis of the body of the uterus have been described by Ozenne: (1) The ulcerating gummatous type, which causes a marked increase in the size of the uterus; (2) the sclerotic type, in which the essential lesions are those of angiosclerosis and fibrosis of the myometrium. Adnexal lesions of which the syphilitic nature has been proven are even rarer than syphilis of the body of the uterus. Special interest therefore attaches to the case described by Dr. Portis, which occurred in a woman aged 38, in whom panhysterectomy was performed in the belief that the condition was carcinomatous. The syphilitic character of the process, however, was proved by histological examination, which showed a chronic diffuse interstitial endometritis, metritis, and perimetritis, with the specific organism in the cellular tissue separating the muscle bundles. The body of the uterus had probably become involved by direct interstitial invasion from a primary lesion on the cervix. Involvement of the adnexa was shown by a corpus luteum and the surrounding stroma of the ovary being the seat of lymphocytic infiltration in which a few treponemata were found.

THE TUBERCULIN DISPENSARY FOR THE POOR.

A combative and stimulating brochure[1] with this heading has recently been issued by Dr. W. Camac Wilkinson, who gives an account of the results obtained by his system of tuberculin treatment. The figures he publishes are instructive, and if certain other figures could be added our knowledge of tuberculin treatment would be not a little enriched. It appears that between 1910 and 1912 there were 107 sputum-positive cases treated at the Lambeth Tuberculin Dispensary. In 1920, 31 of these patients were still alive, 51 had died of tuberculosis and 25 were untraceable. Of the early and moderately advanced cases 68·5 per cent. were still alive, and Dr. Wilkinson compares these figures with those of the London County Medical Officer of Health, according to whom only 28 per cent. survived for four years. It would be interesting to learn whether these 107 sputum-positive patients were selected cases, or if every patient coming to the dispensary was given tuberculin treatment irrespective of the temperature. Again, with regard to the 25 untraceable cases, the question may be raised: Did some of the patients discontinue treatment with tuberculin because they thought it was doing them no good? At the end of his brochure Dr. Wilkinson publishes a short note by Dr. W. Stobie, according to whose statistics 429 cases of pulmonary tuberculosis were treated at Oxford, 83 being given tuberculin and 346 being treated without it. It appears from his table that only 5·2 per cent. of the patients not treated with tuberculin were still alive when this table was compiled, whereas 49·4 per cent. of the patients treated with tuberculin were still alive at the same period. At a casual glance this table suggests that the prognosis is many times better for patients treated with tuberculin than for patients not enjoying this remedy. But Dr. Stobie does not state the principles on which he selected his tuberculin cases. Did every fourth new patient receive tuberculin treatment, the order in which a new patient came to the dispensary being the sole factor determining the selection of controls? Or was the choice of tuberculin treatment determined by the temperature and physical signs? So long as information on these points is withheld, such tuberculin statistics as these are not calculated to impress anyone with more than an elementary knowledge of tuberculosis. Throughout Dr. Wilkinson's brochure there are complaints of the way in which his work has been investigated by the Medical Research Council. This investigation would appear from his account to have been most perfunctory, and if this is the case it is to be hoped that Dr. Wilkinson's work will be given fair judgment after a scrupulous and impartial investigation. He and his assistants have laboured in this particular field for many years, and whether their principles be sound or not, they have, at any rate, made out a case for further inquiries into the action of tuberculin.

THE EFFECT OF INDUSTRY UPON HEALTH.

INSURANCE companies in America have discovered that valuable information lies hidden in their records and are setting an example to other countries by instituting investigations and making the results known. One such review[1] deals with life and health among the wage-earning population of the United States and Canada in 1916–1920, including the end of the war period and the great influenza epidemic. The records of five great companies, which were pooled for the purpose, concern some 26,000,000 men, women, and children aged 1 and over—nearly one-quarter of the entire population of the United States and Canada. The mortality experienced is compared with that of the general population of the United States Registration Area; except that the proportion (46 per cent.) of insured persons under age 20 is greater than that (38 per cent.) of the general population, the age-distribution of the two is similar. The only other variant is that the insured population is composed nearly entirely of whites, while the general population contains a coloured element. One criticism—a serious one—must be made of this admirable study; "the statistics are not shown separately for the sexes because not all the companies had their exposures to risk classified on that basis." Since the mortalities of males and females differ so much, only regret can be expressed.

Some of the more interesting results of this great study may be briefly set out here. The total death-rates of industrial policy-holders throughout life exceeded that of the general population, the excess increasing with age; but over the five years reviewed there was a greater fall in mortality among the industrial population, 14·3 per cent. compared with 7 per cent., and in 1920 the mortality was only 6 per cent. above that of the general population. This result, due to decrease in tuberculosis, heart disease, chronic nephritis, and typhoid, is ascribed in part to better wage and living conditions during and immediately after the war. Tuberculosis in the insured group was less prevalent in childhood, but after age 15, particularly in the mid-period of life, was in excess of the general population. A decline (26·6 per cent.), greater than that (20·3 per cent.) for the general population, occurred in the five years, so that the gap between the two mortalities is being closed. An estimate is put forward that tuberculosis causes a loss in life expectancy of 3½ years for males and 2½ for women, or about 3 years for the two combined, and, further, that a year of life is worth $100 (£20 8*s.* 4*d.*) in net addition to national wealth. Hence tuberculosis is represented to cause a loss of half a billion dollars in the United States; on the same basis of calculation the economic loss in this country would be about £245,000,000 a year. The effect of the influenza epidemic of 1918 is of great interest; it is estimated quite fairly by taking influenza and pneumonia together as one mortality group. The age-distribution of the epidemic was entirely different from the normal for this mortality group which concerns early childhood, then passes at a low level through adolescence and adult life until it increases progressively in late middle life to old age. The great epidemic fastened upon ages 25–34, with ages 20–24 second and ages 35–44 third; upon childhood its inroad was comparatively moderate; in old age normal rates prevailed. This peculiarity is reminiscent of a similar, although less sudden, change in the age-distribution of phthisis during the war period which was manifested in different countries in proportion to their food needs. Probably the two diseases were manifesting a change in resisting power due to food shortage, which by 1918 was affecting even America. The better circumstanced policy-holders suffered least; the group of lives insured on intermediate plans showed a higher mortality; and the group insured on weekly premium plans had the highest rates. The heavier epidemic damage probably arose out of economic and social disabilities. When an alteration in age-distribution occurs, phthisis records teach that the normal is not readily regained, and the influenza-pneumonia records in 1919 and 1920 continue to exhibit a peak in mortality at ages 25–34.

The report rightly dwells upon the importance of organic heart disease, which affected the insured persons more than the general population to about the same extent as tuberculosis; but whereas the excess for tuberculosis is at its height at ages 35–44, that for heart disease has a crest at ages 15–19, which suggests an occupational influence for the former rather than the latter. Mortalities both for chronic nephritis and for cirrhosis of the liver were higher for insured persons, and the excess in each case was greatest at ages 35–44; both showed a great decline, that for nephritis 26 per cent. and that for cirrhosis 57·7 per cent., as compared with 20·7 per cent. and 45·6 per cent. for the general population; the downward trend for cirrhosis is ascribed to diminished use of alcoholic liquors and is regarded as evidence of the effects of prohibition. Typhoid fever, the best gauge of the progress of sanitation, was less prevalent among insured persons, and declined more (49·1 per cent.) than among the general population (42·6 per cent.). The report deals intensively with accidents, animadverting on the increase of automobile traumatism; and with puerperal mortality, wherein the data indicate that the recent rise is attributable entirely to accidents of pregnancy and "other accidents of labour," while puerperal septicæmia and intoxications of pregnancy have remained constant. These are all matters on which British insurance companies could, if they would, give comparable information.

PASSIVE HYPERÆMIA IN THE TREATMENT OF CHOREA.

BIER, when introducing his treatment by passive hyperæmia, laid most stress on his own realms—namely, on surgical conditions—but he also suggested that the treatment might be applicable to cerebral conditions such as epilepsy, chorea, and certain forms of headache, and reported a few observations made in this direction.[1] Since then there appear to have been few, if any, further attempts to utilise his treatment in the cerebral region. Dr. Esau[2] has, however, been using it in the treatment of chorea in his practice in the Krankenhaus Oschersleben-Bode, and reports excellent results. The treatment consists in applying a rubber band round the neck in such a manner as to produce slight congestion of the head, at first for a few hours several times a day, and later when the patient has become accustomed to it, for 22 hours at a stretch. The only unpleasant symptoms arise from the local pressure, and these can easily be overcome by padding the band and by the application of alcohol to the skin. While this treatment was in progress Dr. Esau gave no drugs, nor did he keep the patient isolated, with the exception that in very severe cases he placed the child in an adult rather than in the children's ward. He found that chronic cases responded more rapidly than acute in their first attack. Six cases were treated, one of whom was a girl aged 13, who had suffered from chorea for the last seven years, each attack commencing in December and lasting till the following April. During the attacks every form of medical treatment had been tried, including long spells of isolation in bed, but without result. The child lost weight each time, and only slowly recovered during the summer months. On Jan. 29th, 1923, she was admitted to hospital for an acute attack of appendicitis. She was also suffering from chorea, which had been present since the beginning of December. Operation was successfully performed for the appendicitis, but had no influence on the chorea, which was very severe, and interfered with speech and with feeding. Three days after admission passive hyperæmia was commenced. On Feb. 10th the child lay quietly unless she was disturbed, when active movements of all the limbs took place. By Feb. 26th all choreic movements had disappeared and she was discharged. She was seen again on April 24th, when the general condition was excellent, the parents stating that she was better than she had ever been before. All inclination to whine and cry, which had always been present previously, had entirely disappeared. This case was cured in four weeks, when in former attacks it had taken four to five months. Another child had had two recurrent attacks, and when admitted had been ill for seven weeks, the movements throwing her out of bed, and making walking and speaking impossible. After 12 days' treatment she was able to stand and walk slowly, and in 26 days she was discharged cured. When seen again three months later she was in excellent health, and there had been no recurrence. The other four cases were equally severe and responded as quickly.

[2] Münchner med. Wochenschrift, June 22nd, 1923.

Dr. Esau also carried out a series of observations as to the effect of passive hyperæmia of the head on the general blood pressure. He found that the tendency was for the pressure to rise at the beginning of the congestion, but shortly afterwards to sink to the normal or even below it, but the results were far from constant, and it was difficult to distinguish between changes that were due to the congestion and those that occur normally without it. In some cases the blood pressure sank after removal of the constriction, but rose again shortly after—e.g., B.P. 117 mm. Hg during congestion, 109–105 after discontinuance, and 110–112 a few minutes later, but again these results were not constant, even with the same individual, and further observations on a large scale are necessary to confirm them. The pulse-rate was not affected by the congestion, demonstrating that the intracranial pressure never rose anywhere near that occurring in cerebral hæmorrhage or in meningitis.

PRIMARY CARCINOMA OF THE URETER.

In a report of a case of primary carcinoma of the ureter, with a review of the literature, Dr. Louise H. Meeker and Dr. Joseph F. McCarthy,[1] of the department of pathology and bacteriology and the department of urology of the New York Post-Graduate School and Hospital, illustrate the rarity of this condition, which was first described in 1879, by stating that of the 33 recorded cases in only five was a correct diagnosis made before operation or death; 19 of the cases were in males and 14 in females. The youngest was aged 15 and the oldest 89. Death occurred in 14 instances before operation, some of which were inoperable, and after operation in 11; eight recovered after operation, and two of these reported that they were in good health a year after the operation. As regards the symptoms, the pain is of a relatively atypical nature. In only a small minority was it of the radiating type so frequently encountered in ureteral calculus. It was frequently referred to the lower abdomen, back, sacral and iliac regions, occasionally passing down the leg of the side affected, and was continuous instead of being intermittent as in calculus. On examination of the abdomen a tumour was found in 14 cases and on cystoscopic examination in six cases. In only four cases was pus found in the urine, the absence of pus in the other cases being probably due to the obstructive nature of the ureteral lesion, as hydronephrosis or pyonephrosis is frequently present. In seven instances the discovery of epithelial cells in the urine aided the diagnosis, but the writers point out that it is necessary to make frequent examinations of the urine for atypical cells, especially after attempts at ureteral catheterisation. The occurrence of hæmorrhage on ureteral catheterisation when calculus cannot be demonstrated is also of considerable significance. Chevassu and Mock, who claim to have made the first preoperative diagnosis of primary carcinoma of the ureter, were able to produce bleeding at will, as were also Chiari and Suter. When the ureteral catheter passes the obstruction functional tests frequently reveal renal impairment. A ureteropyelogram is of the greatest value when the obstruction is passed, but if the growth prevents the passage of a ureteral catheter the return of the fluid renders the method useless. The following operations have been performed for the condition: transvesical cauterisation, nephrotomy, resection of ureter and reimplantation twice, with recovery in both cases, nephrectomy with or without ureterectomy, ureterectomy and later nephrectomy, and primary nephro-ureterectomy. The case recorded by the writers was in a man aged 49, who complained of pain in the right hip radiating to the right inguinal and sacro-pelvic regions without any urinary symptoms. Physical examination three weeks before death showed pronounced abdominal tenderness and a cord-like mass in the right hypogastrium. There were marked emaciation and cachexia. The diagnosis was inoperable malignant disease of the colon or ureter. Death took place after six months' illness, and the autopsy revealed a tumour of the right ureter extending from the bladder to the renal pelvis and metastases in the liver, pericardium, lungs, spleen, pancreas, right kidney, lymph glands, and skin. There was right hydronephrosis. Microscopical examination indicated that the tumour had developed from the epithelium lining the ureter.

VENEREAL DISEASES IN NEW SOUTH WALES.

The first report of the Commissioner under the Venereal Diseases Act, 1918, is published as a section of the Report of the Director-General of Public Health to the Minister of Public Health of New South Wales. The Commissioner is Dr. Robert T. Paton, who retired from the position of Director-General on April 30th, 1921, on attaining the statutory age-limit. The period covered by the report is from Dec. 1st, 1920, when the Act came into operation, to Dec. 31st, 1921. The Act aims at ensuring that all cases of venereal disease will have immediate and continuous treatment and requires notification of all cases. A sufferer must place himself under treatment within three days of becoming aware that he is suffering. The Commissioner reports that the provisions have been applied with very satisfactory results, as the following figures show:—

Patients reported for failure to continue treatment ..	2472
Letters returned unclaimed	1286
Number of patients who resumed treatment ..	906
Cases not yet finalised	280

Certain difficulties in working the Act have arisen. Patients changing from one medical practitioner to another have failed to notify the first medical attendant. Patients have given another person's name and address and this other person has naturally resented the receipt of the warning notice. Nevertheless the fact that through the first year's working of the Act 906 persons have returned to treatment is a great gain. The Government provides free treatment at subsidised hospitals and, of 9405 cases notified in 1921, 4477 were notified by metropolitan hospitals. The clinic accommodation has been increased and still further increase is necessary at Sydney and Newcastle. Some of the country hospitals try to send their cases to the metropolis, but Dr. Paton is strongly of opinion that every country hospital should make provision for the treatment of venereal cases. Special drugs and instruments are supplied free to country hospitals and all necessary biological examinations are carried out free at the Government laboratory. The provisions of the Act have stopped the advertisements of quacks and of so-called remedies. Posters and pamphlets are distributed, and Dr. Paton favours "the launching of a broad educative propaganda." He is also in cordial agreement with the resolutions passed by a conference of Commonwealth and States medical officers in Melbourne on Feb. 3rd, 1922, in favour of the establishment of prophylactic depôts as widely in the community as possible and of immediate self-disinfection as a useful auxiliary to the work of such depôts. Dr. Paton recommends a beginning by the establishment of two ablution depôts in Sydney, where information as to self-disinfection should be made available to any person desiring such information. The result of the second year's working of this Act in New South Wales will be awaited with interest.

---

[1] Journal of the American Medical Association, July 14th, 1923.

THE LATE DR. E. K. MUSPRATT.

THE death, in his Grecian house at Liverpool, of Edmund Knowles Muspratt, in his ninetieth year, removes one of the pioneers of applied chemistry. His father, who actually founded the Lancashire alkali industry, sent his youngest son, Edmund, to study at Giessen, where he was attracted by the fame of Liebig, under whose influence he came. The story is told that he witnessed in Liebig's own household at Munich the first application of meat extract to sustain flagging energy in severe illness. Returning to Liverpool, Muspratt threw his immense energy into the heavy chemical industry, and took a large share in bringing it to the prosperous position which it now occupies. He managed for his father the chemical works at Liverpool and at Widnes, which later became incorporated as the United Alkali Works. Muspratt's knowledge of metallurgy was acquired in the cellar at Quay-street, Manchester, which did duty as a laboratory in Owens College, and after his success he donated £17,000 to the University of Liverpool to found the first completely equipped laboratory for the study of physical and electro-chemistry in the British Empire. It was owing principally to his efforts that the scheme took shape to bring to Liverpool water from Lake Vyrnwy, and Muspratt took a large share in the foundation of University College, now the University of Liverpool, which elected him as the first President of Council and as Pro-Chancellor from 1903 to 1909. His high acumen in adapting chemical knowledge to industrial processes was accompanied by unusual appreciation of literature and art, and he was besides a keen and observant traveller in Europe and America. Liverpool has lost in Dr. Muspratt one of her greatest citizens.

SOME CARRIER PROBLEMS.

THE county medical officer of health for Aberdeenshire, in presenting his annual report for 1922, emphasises the danger and expense of diphtheria epidemics, and the most successful method of stamping out the disease. Two epidemics occurred within recent years, one in 1913–14, and the other in 1920–21; expenses in the district hospitals alone in the latter epidemic amounted to £22,000. The number of cases of diphtheria last year was 125, compared with 321 in 1921 and 374 in 1920. Dr. J. P. Watt lays great stress on treatment by the immunisation method with toxin-antitoxin and the Schick test. It was of the utmost importance to stamp out infection in diphtheria carriers, for there was one carrier for every 100 adults and four or five for every 100 children. Much valuable work had been done recently by the Health and Education Departments in New York. Free inoculation with toxin-antitoxin had been given in all the New York schools with most successful results. The report also deals with the treatment of chronic typhoid carriers with detoxicated vaccines. It is well established that epidemics of typhoid fever may originate from a carrier, the typhoid bacilli surviving in the walls of the gall-bladder and kidneys. Such an infection has been found extremely difficult to eradicate. Cholecystectomy is not uniformly successful in bringing about a cure. In view of the successful treatment of chronic nasal diphtheria carriers at Summerfield Hospital with detoxicated diphtheria vaccine, Dr. Watt determined to treat chronic typhoid carriers with a course of detoxicated typhoid vaccine. To one carrier of 20 years' duration injections were given subcutaneously every fifth day; at the end of three months typhoid bacilli were still present; at the end of six months an atypical bacillus, which did not agglutinate. After a second course of treatment by injection and also orally, this bacillus disappeared and all samples were negative. Dr. Watt hesitates to draw conclusions as yet from such treatment, as typhoid carriers may be "negative" for considerable periods. Many samples must be examined over an extended time before a definite cure can be claimed. But his observation is suggestive.

PRURITUS OF THE ANAL REGION.

A NICE distinction in nomenclature is suggested by Dr. J. F. Montague, who classifies[1] under the two headings of Direct and Indirect all types of pruritus of the anal region; he reserves the term Pruritus Ani for direct cases—i.e., those in which there is a local irritant such as a fissure—and styles the indirect cases anal pruritus. He explains all cases of indirect pruritus—i.e., those which occur in the absence of any local lesion or irritant—as due to the transference of an irritable stimulus from visceral afferent nerves to somatic nerves with a consequent misrepresentation or error in localisation of the resultant sensation, and gives the following anatomical explanation. The pruritic zone is supplied by sensory nerves from the first four sacral nerves, which are in intimate neural connexion with the pelvic and other abdominal viscera, through the aortic and hypogastric plexuses and when a viscus is the seat of chronic inflammation, congestion, and hypertrophy the mechanical tension sets up efferent stimuli which the spinal cord misunderstands. He points out that indirect pruritus is not relieved by local anæsthesia, as is the case with the direct type, but, unfortunately, the indirect soon has the direct grafted on it when the patient has developed the scratching habit. The pathology of pruritus is in the main so obscure that we welcome any attempt at its elucidation.

---

[1] The Etiology and Pathogenesis of Anal Pruritus and Pruritus Ani, Transactions of the American Proctologic Society, 1922.

THE Medical Branch of the Board of Education has been transferred to 54, Victoria-street, London, S.W. 1. The telegraphic address is "Meducation Sowest, London."

MEDICAL REPRESENTATION IN THE NEW DAIL.—The elections in Ireland have resulted in the return of a larger number of medical men than sat in any previous Dail. Of those who were members of the last Dail, two—Dr. P. McCartan, who did not seek re-election, and Dr. V. White, who was unsuccessful—are absent. Among the independent members Sir James Craig, F.R.C.P.I., and Dr. Myles Keogh, retain their seats, as does also Dr. R. Hayes, of the Government Party. The Republican, or Sinn Fein, party contains no less than five medical practitioners—Drs. J. Crowley, P. McCarville, O'Byrne, J. Ryan, and Kathleen Lynn. The last-named is the first woman doctor elected to any Parliament in the British Islands. It is not yet known whether the members of the Sinn Fein party will take their seats, and therefore one cannot foretell what effect on health policy the presence of so many doctors in that party may have.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XXXV.

THE TREATMENT OF ENURESIS.

There is none of the minor ailments of children which has so marked an effect on the moral and mental well-being of a child, and in later years on his material prospects, as the habit of nocturnal incontinence of urine. It is a troublesome complaint both to the parents, the patient, and to the doctor who is called upon to treat it. Although from time to time the virtues of some chosen therapy are proclaimed, consideration of the physiological aspect of micturition makes it obvious that there can be no one method or drug which can be relied upon to improve the trouble. In the infant the evacuation of the bladder is purely a reflex act. Almost any conceivable stimulus is sufficient to excite the centres in the spinal cord which control the act of micturition, with the result that the bladder contracts and evacuates its contents completely. During the first year of life this is the normal condition, and it is frequently prolonged into the second year. A careful nurse can, however, often train her charge in such a way that by the end of the fifteenth month the spontaneous evacuation of the bladder is a comparatively rare event; and except for accidents or illness incontinence is uncommon after the end of the second year. The training which will accomplish this result is, of course, largely attention to the proper evacuation of the bladder at regular intervals. If after the age of 2 years enuresis or precipitate micturition during the day is present it must be considered as no longer a physiological but a pathological phenomenon.

Enuresis in young children is usually dependent on a reflex contraction of the bladder, but exceptionally the symptoms suggest an overflow incontinence; the child is said to "drip like a tap." It is probably this type which has led some observers to talk about the failure or absence of the sphincter, and to suggest various kinds of local treatment based on this supposition. In fact, in those cases of this type which I have seen I do not think that there has been any reason to suppose such a failure; they regained control with ordinary treatment quite as rapidly as the more usual type. Another condition which is much more difficult to treat successfully occurs in the children at or even after puberty, in whom incontinence has existed for some years. In them the bladder appears to have reached a condition of extreme local irritability, which makes it impossible for the urine to be retained for more than a few minutes at a time. Such unfortunates have almost reached the same state as the child who is afflicted with extroversion of the bladder. My experience, however, is that even with these patients something can be done. These cases of "dripping like a tap" and of "vesical spasm" are not the common type. The majority belong to the "reflex contraction" group. These patients nearly always, besides the nocturnal enuresis, have precipitate micturition during the day, and it is that symptom which must be first tackled.

There are two groups into which the children who are brought with enuresis can be divided. The group (A) which is congenital—that is, in which the normal control which should come by the end of the second year has never been attained; and the group (B) which has an acquired condition—that is, in which the normal control has been gained and subsequently lost.

The Congenital Group.

In the first group will be placed the children who suffer from congenital defects, whether physical—for example, extroversion—or mental. It is obvious that very little can be done for them. It will also include the children who suffer from minor epilepsy; who, perhaps, have never had a fit, but whose history, when carefully and fully considered, contains suspicious details. One such suspicious fact is the intermittence of the enuresis. The child will go for some considerable time without enuresis, and then have a series of accidents within a week or two, after which he will again be untroubled. If with such symptoms there is a story of inattention, or giddiness, or attacks of dazedness the probability of epilepsy being the cause is enhanced, and in such instances the use of bromides in small doses is, as a rule, effective. When these cases are exhausted there are still left a considerable number in whom there is no obvious reason for the continuance of the incontinence; they are cases of so-called "essential enuresis."

Acquired Enuresis.

The same will be found true of the second group of acquired enuresis. In some few of such cases it is possible to discover an obvious exciting cause. For example, in some of the older school-girls there is a chronic intermittent *B. coli* pyelitis and cystitis, the treatment of which will stop the enuresis. In others there is some traumatic cause—for example, the presence of a stone in the urinary tract (incontinence may be the only symptom of its presence); in rare instances there may be tuberculosis of the tract, or a reflex excitability may have been established by the existence of a balanitis or a vulvitis. But in the majority there is no obvious cause; they are cases of "essential enuresis."

Essential Enuresis.

Essential enuresis is the persistence of, or return to, the reflex condition of the infant; and though the removal of some of the more obvious exciting stimuli may in some lucky cases effect a dramatic cure such a result is not very common. Often the removal of adenoids has been held out as certain to stop the urinary trouble, which all the same persists; the presence of worms in the large intestine has been held responsible, but their effective treatment has not removed the enuresis. Dietary treatment has been given without good effect. All these things are part of any effective treatment, but nothing in my judgment can replace the re-education of the child just as if he or she were a baby in the second year. The education must begin by teaching the child to control the bladder during the day. If the water can be retained for a period of two hours only, then every two hours the bladder must be properly emptied. After a few days, when the excitability is lessened, the period can be lengthened to three hours, and it must be forbidden to the child to perform the act at any other than the stated time. This is a prescription which sounds more difficult to carry out than it is found to be in practice. The interval is then lengthened to four and five hours, and then lastly to three times in the 24 hours. By the time that the child has learnt to control micturition during the day to this extent the nocturnal enuresis will, as a general rule, also have disappeared, but its disappearance can be helped by some simultaneous attention to this part of the trouble. It will be found on careful inquiry that most of the children who wet the bed do so in the first two hours of sleep. If they are wakened at the end of an hour and made to empty their bladder it often happens that the rest of the night will be dry. It is not always so, and it may be necessary for a short time to waken them every three hours, but with the increasing control during the day the nocturnal symptoms become less severe.

This method of training in a nursing home or a hospital is generally successful in a short time, a month or even less, but too often there is a relapse because the punctuality of an institution is not observed at home. However rapid and complete the apparent success, the method of training should be persisted in for at least six months.

Training is, I think, the one essential without which all else is likely to be useless, but there are various adjuvants. There should be no attempt to restrict the intake of fluids, a step which leads to the secretion of a highly concentrated urine, likely to be exciting to the bladder—in fact, I think it is advantageous to promote diuresis by the administration of potassium citrate. There are also some other drugs which I have occasionally believed to be beneficial. The first of these is strychnine given as liq. strychninæ in doses which are large for the age of the child; I should, for example, give ♏ v.–vii. three times a day to a child of 6 years, for a week at a time. The second is thyroid, which I like to give to those children who are lethargic and inactive; the bright, energetic, excitable child is better without it. I use doses of gr. 1–3 twice a day. The third drug is belladonna, a time-honoured remedy, usually given in too small doses; to be efficacious it requires to be given in such doses as will produce a physiological effect, either in complaints of dryness of the mouth and throat or in loss of accommodation. Children vary much in their tolerance of this drug, and the proper dose must be ascertained for each case. It is safe to begin with a dose of ♏ x. of tinct. bellad. three times a day, increasing this rapidly till the physiological effect is obtained. Another drug which I have occasionally found useful is potass. chlorate. Why it should have any effect I cannot tell, but I have satisfied myself that it is of benefit in some cases. I have used many other drugs and failed to find any of value, though iron and arsenic are, of course, useful where there is a need of tonics. As regards diet, I think there is profit in a prohibition of sweets, and also in reducing, if need be, either the starchy or the nitrogenous parts of the meals—that is, in stopping over-feeding.

With such methods I think the prospect of success is good in about 75 per cent. of the cases of essential enuresis within a period of six months. Of the remaining 25 per cent. the majority can be cured by persistence in treatment over longer periods up to two years, but there is a small percentage in which the condition continues, apparently without appreciable improvement, up to puberty. In a very few cases, chiefly in girls, it may persist into adult life. Electrical treatment has proved disappointing in my hands, whatever the method adopted, and the same is true, so far as my own small experience goes, of any form of psychotherapy.

BACTERIOLOGY OF CONDENSED MILKS.

A REPORT[1] TO THE FOOD INVESTIGATION BOARD.

THIS long report, of 103 octavo pages, deals with both varieties of condensed milk, but the two reports are quite distinct and the scientific problems in the two cases are very different. Both are essentially bacteriological studies, and methods of manufacture, chemical composition, &c., are only briefly discussed in so far as they are required to make the bacteriological findings intelligible.

SWEETENED CONDENSED MILK.

All the samples examined were of the full cream variety. A short study is given of the methods of inspection adopted at the ports of entry on lines similar to those given in previous reports on canned meat and marine products. With blown samples no difficulties were met with, but the judgment of the inspectors as regards springy and otherwise defective tins was only correct in about half the cases. These tins are not, however, of great importance, since the majority of rejects are due to gaseous decomposition.

The bacteriological studies are based upon a detailed examination of 95 samples of which 33 were "blown" rejected tins, 13 rejected for other physical conditions, 15 sound shop tins, and 34 sound factory tins, the latter being tins obtained direct from condensed milk factories passed as sound, the exact date of manufacture being known. In addition, 32 samples of sugars, fresh milk used for condensing, air samples, or deposits from pipes in the factories were examined. A large number of experimental tin inoculation experiments were also carried out.

Organisms Isolated and Their Significance.

Sweetened condensed milk is never sterile and the distribution of yeasts, micrococci, anaerobes, gas-producing aerobic bacilli, sporing aerobic bacilli, and thermophilic bacteria are separately considered. The report shows that the relative importance of these groups are very different. Apart from the possible presence of tubercle bacilli and perhaps some types of streptococci, none are of pathogenic significance. Micrococci were present in every sample of sweetened condensed milk as streptococci, staphylococci, and diplococci. They are in part survivals from the original milk in part gaining access during manipulation after condensation. Anaerobes, on the other hand, were only found in 2 out of 76 tins. While both were from infected tins direct experiment showed they were not a cause of unsoundness. The physical changes consequent upon condensation makes the milk an unsuitable medium for their growth. Gas-forming aerobic bacilli were isolated from 7 tins, or 9·3 per cent., of the samples examined. All were *B. coli* strains almost identical, all fermenting both lactose and saccharose, and so potential causes of the blowing of tins, particularly as they grow well anaerobically. Numerous experiments, including direct inoculation of tins, showed that while their growth is not inhibited by 40 or even 50 per cent. of saccharose they will not grow and ultimately die out in condensed milk. Either from its viscid nature or from some other cause it is a medium unfavourable to their growth and viability. These results were in accordance with the distribution of the organisms in the samples and suggest that this type is not a cause of unsoundness in this food product.

Considerable interest attaches to the group of sporing aerobic bacilli, since they were isolated from 92 per cent. of the tins, while the authors consider they are probably present in every sample. In view of their ability to decompose milk and proteins generally, they are potential causes of decomposition. On the other hand, their wide distribution in tins, sound and unsound alike, suggests that they do not, in fact, do so, and this was confirmed by a number of direct experiments. These showed that their harmlessness was not due to the anaerobic conditions to any material extent and only very partially to the high percentage of saccharose, but must be ascribed to the colloidal changes in the milk produced as a result of condensation. Under the three conditions combined they are incapable of producing any decomposition or proteolytic changes in the milk. Thermophilic bacteria, all of sporing type, were isolated from 76 per cent. of the samples examined and were found to be of no significance as a cause of decomposition. They are probably survivals from the original milk.

Yeasts.

On account of their great importance special attention was given to this group of organisms, and over 22 pages are devoted to a detailed study of their presence, distribution, and significance in this type of condensed milk. Yeasts were present in 91 per cent. of the "blown" tins examined, and this condition is almost invariably due to the growth and chemical activities of yeasts. The problem, however, is not the simple one of unsoundness being due to their presence alone since yeasts, including many fermenting yeasts, were isolated from many sound factory samples and were shown not to originate decomposition changes. The yeasts isolated were grouped under seven different types, the chief points of importance being their fermenting properties as regards saccharose and lactose and their ability to grow in 40 and 50 per cent. saccharose solutions. That fermenting yeasts under suitable conditions can cause tins to become blown was amply demonstrated by numerous direct experiments in which sound tins were inoculated. A long series of experiments, using special forms of apparatus, enabled a coherent and practical explanation to be given of the prevalence of even fermenting types of yeasts in sound samples of condensed milk. Living yeasts may be widely distributed in condensed milk even when manufactured under modern and scientific conditions. Yeasts do not readily multiply in such milk. This is not due to the high percentage of saccharose, is in part due to the fact that condensed milk is a medium not very suitable for their growth, but is chiefly because of the restricted supply of oxygen. "In tins of condensed milk the supply of oxygen available is very limited and is soon exhausted. If the yeasts are present in sufficient numbers, or if they can multiply sufficiently with the little oxygen available, then they will be able to produce sufficient enzyme to break down the saccharose and produce gas. They are then comparatively independent of any oxygen supply and need not go on increasing materially in numbers, but their enzymes can steadily produce gas." If only a few fermenting yeasts gain access they are unlikely to produce gas and cause the tin to become blown, because they will not increase sufficiently before anaerobic conditions become established in the tin, thus causing their multiplication to cease. Under such conditions they gradually die out. These facts are of great practical importance in connexion with the prevention of unsoundness and suggest many points of importance in manufacture.

[1] Studies in Sweetened and Unsweetened (Evaporated) Condensed Milk. By William G. Savage, M.D., B.Sc., and R. F. Hunwicke, B.Sc., A.I.C. Department of Scientific and Industrial Research. Food Investigation Board. Special Report No. 13. H.M. Stationery Office. 4s.

A study of their source showed their invariable presence in the air of the condensing factories, and this and their survival in the milk used, due to insufficient preliminary heating, must be regarded as their main sources. An important source keeping up their supply is from deposits in the pipes leading from the vacuum pans, as after the milk has been pasteurised it is never again subjected to temperatures high enough to secure the destruction of yeasts.

Changes on Keeping.

A long series of observations were made upon changes in bacterial content, acidity, colour, and consistency under different conditions. The average number of organisms per gramme was usually low in fresh samples and fairly uniform considering the consistency of the material. When tins were kept *unopened* at 21° C. and 37° C. there was usually a diminution rather than an increase in the number of organisms, but when a small amount of sterile air was admitted the number of organisms showed a marked increase for the first two weeks or so, followed by a diminution, so that at the end of about three months the numbers were often less than at the start.

No facts of special interest were elicited as regards acidity and H-ion concentration changes with time. The darkening in colour was not associated with bacterial activity, and is probably due to caramelisation of some of the sugar. It took place much more rapidly at higher temperatures. The thickening and increased viscosity which takes place with time showed no relationship to changes of acidity or bacterial activity and were colloidal in character.

Practical Considerations.

There is no suggestion that the bacteria and yeasts which are present and which are the subject of detailed study are harmful to the consumer, and the report is mainly of interest as a detailed study of the causes of unsoundness and the prevention of wastage and food loss. Compared with new cow's milk condensed milk is a food of very low bacterial content. The report does, however, supply much scientific information into the causes of condensed milk decomposition and how to prevent such deterioration. The practical points indicated as of the greatest importance are the necessity to ensure the destruction of yeasts in milk before condensation, cooling the milk under conditions which avoid air contamination, the use for the condensed liquid of suitable right-angle pipes taken apart and sterilised every day, canning of the milk as soon as possible after condensing, and in particular the use of airtight containers.

Unsweetened Condensed Milk.

For this food it is pointed out that correct condensation offers many difficulties, and the margin between success and failure is probably a narrower one than for any other type of canned food. A brief account of methods of manufacture is given. The bacteriological studies are based upon the examination of 104 different samples—rejected, shop, and sound factory samples. This type of condensed milk showed a much higher proportion of sterile tins, the actual percentages being 85 for the shop and 76 for the factory tins. The organisms found were most commonly sporing aerobic bacilli, but also micrococci and one yeast. No physical alterations were noted in the contents.

Of the 60 rejected tins 47 showed definite abnormalities in the contents. It is of interest to note that the causes of the unsoundness were very different from those found with the sweetened variety. Yeasts were unimportant and only a cause of unsoundness in one sample. Sporing anaerobes accounted for 3, micrococci for 18, gas-producing aerobic bacilli of *B. coli* and *B. cloacæ* type for 6, and a special type described as "coccoidal bacillus" type for 5. The cause of decomposition was not ascertained in the remaining tins and 7 of them were sterile. The experiments carried out do not support the possibility that chemical changes are ever a cause of a blown condition. The suggestion that micrococci may not only cause decomposition changes in the contents but even the development of gas is a new conception, but is supported by a number of experiments in which it is shown that under special conditions the micrococci selected did produce gas from unsweetened condensed milk. The gas produced was carbon dioxide and the blown condition could not therefore be ascribed to hydrogen developed from the chemical action of the milk on the tin retainer.

The coccoidal bacilli constitute a new type which show marked pleomorphism. The authors mention that they have found it rather prevalent in unsound canned fruit as a cause of unsoundness.

Practical Considerations.

The conditions which may produce unsoundness are complex and not merely a question of the presence or absence of certain types of bacteria, since there are some types which at one time are inert while at others they make the food unsound. The changes in the condition of the milk as a result of its concentration are profound and not merely those caused by a deprivation of much of the water. The milk so altered is in general less suitable for bacterial multiplication. The manufacturer has many difficult problems to contend with, and very slight differences in the temperature of sterilisation and slight changes in acidity may yield a coagulated useless product. It is doubtful whether the temperatures of processing which can be adopted without risk of damaging the product are capable of always ensuring a sterile product. Probably in many cases a few spores are left undestroyed. The results of the authors show, however, that decomposition is nearly always due to non-sporing bacilli, and that what the manufacturer has to guard against are the survival of non-sporing bacilli (especially the more resistant types of micrococci) and the admission of air through minute leaks which may enable dormant forms to multiply and cause decomposition changes.

ARSENICAL POISONING.

THE WORK OF THE SWEDISH COMMISSION.

SOME years ago the Swedish medical profession and, to a certain extent, the lay public were much exercised over the part played by arsenic in wallpaper, clothing, and domestic articles, and the discussion of this subject led to the appointment by the Swedish Government of a Commission composed of chemists and doctors. Prof. K. Petrén, of Lund, presided over this Commission and was in special charge of the clinical side of the investigations. These were not merely concerned with sifting evidence already available; new and important researches were undertaken, and some of them have thrown valuable light on the problems of arsenical poisoning. In a recent communication published in French, Prof. Petrén[1] has given a summary of the most instructive findings of the Commission. Simultaneously a 240-page monograph has been published in German by his collaborator, Dr. L. Brahme,[2] whose researches deal with the presence of arsenic in the blood and cerebrospinal fluid. Another investigator, Dr. Bang, who has recently died, carried out systematic examinations for arsenic in the urine of healthy persons. His work was published in 1919 in Swedish,[3] and a short summary is given of it in Prof. Petrén's paper.

House Poisoning with Arsenic in Sweden.

The term "house poisoning" covers poisoning by arsenic from such sources as wallpaper, clothing, articles of furniture, stuffed birds, and the like. Inquiries addressed by the Commission to Swedish practitioners as to the occurrence of cases of house poisoning elicited records of 91 cases, but when these came to be scrutinised very few were found to be proven. The same observation was made when the literature of the subject was sifted, and it was found necessary to fix certain standards and criteria by which the genuineness of cases of arsenical poisoning of this class could be judged. For arsenical house poisoning to be diagnosed it must, among other things, be proven that the symptoms began within one to three months of exposure, and ceased within three months of the cessation of such exposure to house poisoning. In this connexion it is not conclusive evidence of house poisoning that a patient loses his or her symptoms after leaving a room in which arsenic has been found, for there may have been other morbid influences at work in this particular room.

The Literature of House Poisoning.

Prof. Petrén's excursions into the literature of the subject revealed the curious fact that it has appeared and reappeared in different countries in batches; in Sweden the period 1850–81 yielded a large batch of publications. In Germany similar publications were practically confined to the period 1853–81, and in the Anglo-Saxon countries to the period 1853–92. Altogether about 125 publications were found to be worthy of special scrutiny, and even in this sifted material much evidence of doubtful value had to be discarded. Only 36 Anglo-Saxon, 8 German, and 17 Swedish publications contained reliable data, and it was noteworthy that comparatively recent observations were, on the whole, those on which least reliance could be put.

Differences in the Manifestations of Poisoning by Arsenic from Various Sources.

It is a very remarkable fact that the symptoms of poisoning vary greatly according as arsenic is taken by the mouth, is absorbed by workers in arsenic, or enters the system as the result of house poisoning. When arsenic is taken in large doses by the mouth, melanosis and polyneuritis are prominent sequels, whereas melanosis has never, and polyneuritis has rarely, been observed in cases of house poisoning. On the other hand, workers in arsenic, in contact with Schweinfürth's green, are liable to suffer principally from cutaneous lesions such as erythema, papular and pustular eruptions, and even gangrene. These manifestations are practically unknown in cases of poisoning with arsenic given by the mouth, and it is therefore probable that in industrial arsenical poisoning the arsenic acts directly on the skin, the face, neck, and hands being the parts most affected. No case of industrial arsenical poisoning has yet been recorded in which melanosis was seen. Arsenic given by the mouth provokes digestive disturbances such as diarrhœa and also conjunctivitis, whereas in house poisoning the principal symptoms are lassitude, headache, giddiness, and irritation of the eyes and pharynx. Diarrhœa is comparatively rare and only in a few cases has polyneuritis been observed. The manifestations of these three different forms of arsenical poisoning being so distinctive, it has been suggested that in house poisoning some volatile compound of arsenic is responsible for the symptoms. Working on this suggestion, a member of the Commission, Dr. M. Ramberg, professor of chemistry, carried out investigations with regard to the development of arsenical gases from the action of arsenic on certain moulds. He came to the conclusion that the composition of the gases thus generated is inconstant, and he was unable to confirm Biginelli's hypothesis that the arsenical gas generated under these conditions is diethylarsine. Prof. Ramberg's and Prof. Petrén's last conclusion in this matter is that in arsenical house poisoning several highly toxic substances are concerned, the composition of which is still unknown.

Arsenic in the Urine of Healthy Persons.

One of the most important of the researches carried out under the auspices of the Commission was concerned with the demonstration of arsenic in urine of healthy persons. Until Dr. Bang began his investigations in this matter, it was generally held in Sweden that the demonstration of a certain quantity of arsenic in the urine was equivalent to the demonstration of arsenical poisoning. Little or nothing was known of the conditions under which, in health, the arsenical content of the urine might vary. After devising a new and delicate test for arsenic in urine, Dr. Bang found that the arsenic in normal urine might vary from a trace to 1 mg. per day. The great and rapid changes in the arsenical content of normal urine led Dr. Bang to investigate the arsenical content of various foods, and he found that while some vegetables contain little arsenic, others contain much. The amount of arsenic found in fish varied considerably, but in most cases it was amazingly great. The differences in the arsenical content of fish seemed to depend largely on the water in which they lived; some sea-water fish contained as much as 4 mg. per kilo. This discovery largely explains the inconstancy of the arsenic content of normal urine. At Prof. Petrén's hospital Dr. Bang examined for arsenic the urine of patients fed for a certain time on such articles of food as milk, cream, oatmeal, and eggs, which are poor in arsenic. While they were on this dietary their urine contained only traces of arsenic. But when, on several consecutive days, they were given a liberal dietary of fish, the arsenic content of their urine rose rapidly, and it fell again when the fish dietary was withheld.

Other Findings of the Commission.

A matter to which Prof. Petrén returns frequently in his paper is the great difference in the toxicity of various compounds of arsenic, and the differences in the reaction of the body to the same compound. In the case of salvarsan, for example, the reaction of the body would seem to depend to a certain extent on the nature of the pre-existing infection, and the reaction of syphilitics to salvarsan is probably peculiar to this class of case. Prof. Petrén gave neosalvarsan to patients suffering from influenza during the epidemic of 1918 and found that the first and only toxic effect was vomiting—an observation suggesting that the response of the influenza-infected body to salvarsan differs from that of the syphilitic patient. One of Dr. Brahme's most interesting observations referred to the behaviour of arsenic in relation to the cerebro-spinal fluid. He confirmed the observations of Tinel and Leroid, who found that while arsenic cannot reach the cerebro-spinal fluid through healthy membranes, it may do so when these membranes show morbid changes. Several other lines of research were followed by the Swedish Commission, the work of which has added not a little to our knowledge of the toxicology of arsenic and its compounds.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table gives some of the principal health statistics of seven large towns for the year 1922:—

Name of town.	Estimated population (mid-year).	Birth-rate.	Death-rates per 1000 of population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Respiratory with influenza.	Infant mortality		Maternal mort. in childbirth.
							Legit.	Illegit.	
Edinburgh ..	423,155	20·7	15·2	1·3	1·5	2·6	88	128	3·8
Blackburn	129,376	16·8	14·2	0·9	1·3	3·8	97	140	7·0
Hull	294,000	24·2	14·4	1·4	1·2	3·7	101	210	3·9
Leicester	238,800	19·4	12·7	1·5	1·2	2·6	85	141	3·0
Portsmouth ..	236,630	22·1	12·1	1·1	1·2	2·3	61	100	2·6
Preston	120,900	20·5	13·7	1·2	1·0	3·4	96	129	4·8
Stockport	125,800	17·4	13·4	1·1	1·3	3·7	76	96	7·3

All these towns suffered from the influenza epidemic during the first quarter, but it is perhaps justifiable to attribute the lessened fatality of respiratory diseases in Edinburgh, Leicester, and Portsmouth to the cleaner air when comparison is made with Blackburn, Preston, and Stockport. The three last-named towns also show a high maternal mortality in childbirth. The effect of the boot and shoe trade is no doubt seen in the tuberculosis mortality rate of Leicester. The table brings out the fact that cancer now frequently causes more deaths than all forms of tuberculosis and the marked difference that still exists between the mortality of illegitimate and legitimate infants, in spite of maternity and child welfare work.

Edinburgh.

Dr. William Robertson presents the report for a year during most of which the late Dr. Maxwell Williamson was medical officer of health, and in doing so suggests that future policy must be directed at prevention in its fullest and most literal sense. Edinburgh, he says, has splendidly equipped institutions for coping with epidemic diseases and tuberculosis, and it should now be our aim to reduce the demands on these institutions. Dr. Robertson looks forward to the ensuing years when big improvements in Edinburgh housing conditions may be confidently expected. "No matter in which direction he may turn, the sanitary reformer will always find the spectre of the housing problem facing him."

Dr. T. Y. Finlay's report on child welfare mentions that the Toddlers' Play centres continue to fulfil a useful and necessary piece of work. Of 58 notified cases of ophthalmia neonatorum, one case had both eyes damaged and in two cases it was recorded that previous children in the family had been affected by the disease. Dr. John Guy, the tuberculosis officer, shows that the decline in pulmonary tuberculosis was only retarded, but never ceased, during the war, and that in 1922 the number of deaths was the lowest ever recorded. It is admitted that Edinburgh and Glasgow suffered less from fat restrictions during the war than English towns, and one wonders to what extent this factor accounted for the very varying results obtained as between one town and another. Dr. Guy emphasises the importance of milk as a cause of non-pulmonary tuberculosis, and states that 30 per cent. of gland cases, 18 per cent. of meningeal cases, 50 per cent. of abdominal, 58 per cent. of bone, and 50 per cent. of lupus cases are due to this cause. The importance of segregation of infectious cases is insisted upon and an estimate is given that, at present, infectious cases are segregated during one-third of the period of infectivity

Dr. Claude B. Ker mentions that the staff of the City Hospital has been subjected to the Schick test and that those who gave positive reactions have been inoculated with toxin-antitoxin mixtures. Mr. David Lees, the V.D. medical officer, states that there is a marked improvement in the attendances and the number of cases completing treatment. There is, however, urgent need of a treatment centre and hostel accommodation for merchant seamen near the docks, in order to secure continuity of treatment.

Blackburn.

Dr. W. Allen Daley's report shows that the Blackburn Corporation is actively engaged in improving sanitary conditions. Nearly 9000 pail closets have been converted into water closets or abolished since 1920. Blackburn is supplied with water from upland gathering grounds. An investigation of the plumbo-solvent properties of the water was undertaken during the year. The public analyst, Mr. W. H. Roberts, reports that the water is soft, of good quality, and practically neutral, and that its action on lead is so slight as to be negligible. Dr. Daley reports a shortage of houses. The Corporation completed 89 houses during the year. Applicants show a preference for non-parlour houses. There is some serious overcrowding and over 100 houses are past repair, but cannot be closed. There is considerable undesirable subletting, and Dr. Daley thinks there is a demand for small cottage flats. A campaign is in progress against the smoke nuisance and another in favour of clean milk. Energetic steps are being taken to improve the ventilation and hygiene of the cinemas. Attention is being given to the better protection of food from contamination. Particulars are given of the present condition of consumptive patients discharged from the Blackburn Corporation Hospital and Meathop Sanatorium during past years. In the case of the former, 82 of 709 patients discharged since 1913 are at full work, 350 are dead, and 96 cannot be traced. In the case of Meathop, 63 of 445 patients discharged since 1908 are at full work, 177 are dead, and 79 cannot be traced. The window-cleaning business managed by the Charity Organisation Society for ex-sanatorium patients is in a prosperous condition. Dr. Daley comments on the high mortality associated with childbirth and looks to efficient and popular ante-natal clinics, combined with adequate maternity home accommodation, to bring about an improvement. The maternity home accommodation will be increased during 1923.

Hull.

Dr. J. Wright Mason reports that the maternity and child welfare work has been reorganised under a whole-time medical officer, Dr. Katherine Gamgee, who began work in June, 1922. Attention is called to the high death-rate among babies suffering from ophthalmia neonatorum and the laxness of the midwives in notifying this condition. Comment is made on the high infant mortality rate and the fact that Hull compares badly with other towns during 1922 with respect to diarrhœa. 334 municipal houses were completed during the year. On account of the housing shortage, many older houses, intended for one family only, are now being occupied by two or more families.

Leicester.

Dr. C. Killick Millard reports three important events during 1922—viz., the retirement of Alderman Windley after 46 years as chairman of the Health Committee, the retirement of Chief Sanitary Inspector Braley after 50 years' service, and the decision to acquire new premises for the Health Department outside the Town Hall. Alderman Windley's service has been commemorated by the establishment of four secondary school scholarships named after him. Dr. Millard thinks the housing shortage may have increased the marriage rate. Formerly young people "saved up" for furniture. Now they need not wait "to save up."

The Leicester leaflet giving elementary facts with regard to cancer has aroused many expressions of approval. Dr. Millard would like to see a campaign started to bring home to the public the disastrous effects of dental caries. His remarks deal chiefly with early treatment. The leaflet on prevention published in our issue of August 4th (p. 265) might well form a basis for such a campaign. Leicester, unlike Edinburgh, showed a very definite increase of deaths from pulmonary tuberculosis during the war, but the average number of deaths for the four post-war years is lower than that for the four pre-war years.

An open-air school is needed in Leicester. Very good work has been done by the seaside summer camp at Mablethorpe, where 593 children spent a fortnight last year. Dr. Bessie Symington, M.O. of the Women's V.D. clinic, reports that great efforts have been made to persuade mothers to come up for treatment during pregnancy. None of the 26 syphilitic mothers treated gave birth to a diseased child. In spite of the fact that both maternity homes have ante-natal clinics, it was not possible to persuade any of the mothers attending these ante-natal clinics to go for treatment to the V.D. clinic. This confirms he view of those who think that in order to secure adequate treatment of the expectant mother suffering rom venereal disease, it is necessary to provide such treatment at the ante-natal clinic. The health committee have decided to obtain Grade A (tuberculin tested) milk for the Isolation Hospital Sanatorium, maternity home, and day nursery. Although visitors from northern towns regard Leicester as a clean-air town, it is pointed out that there is considerable room for improvement as regards smoke abatement. "Shortage of housing accommodation," says Dr. Millard, "remains Leicester's most crying need."

Portsmouth.

Dr. A. Mearns Fraser says the one subject above ll others to which he must specially refer is the urgent necessity for the provision of housing accommodation. He believes that the problem can be olved by the rapid development of the splendid site n Portsdown Hill (524 acres). The Corporation ave completed 543 houses, but the position is hardly ess acute than it was two years ago. There are 000 urgent applications for houses, many unfit ouses cannot be closed, and one unhealthy area, ncluding some deplorable houses, cannot be dealt ith. The Portsdown Hill site Dr. Fraser regards s ideal, and he would have every effort made to induce rivate builders to develop it. In six of the 17 notified ases of enteric, improperly cooked local shell-fish, ockles, winkles, and butter-fish, were suspected as he cause. The war rise in the death-rate from ulmonary tuberculosis is well brought out by a hart. Since the war the rate is lower but tends to be tationary, and the greatest hope for the continuance f the decline lies, Dr. Fraser thinks, in an improvement in housing and the development of the Portsdown Hill estate. During the year 12,000 gallons f electrolysed sea-water disinfectant were manufactured by the municipality. The public analyst, r. Reginald P. Page, lays stress on the fact that the ddition of chemical preservatives to food is steadily n the increase, and instances samples of "home-made" mincemeat, containing no spirit preservative ut salicylic acid.

Preston.

Dr. F. A. Sharpe says the shortage of houses is not causing numerical overcrowding because the population is practically stationary, but that it is causing the loss of comfort, domestic necessities, and decencies, owing to the housing of more than one family in a house. One of the great needs of Preston is a home nursing service. In December, 1922, an unsuccessful attempt was made in the committee to reduce the permissible limit for black smoke emission from factory chimneys. There are about 135 factory chimneys in the borough and they are apparently permitted to emit five minutes of black smoke every half hour. Fortunately they do not all avail themselves of this privilege. Several of the seven proved cases of enteric fever were attributed to polluted mussels. There was a slight increase both in notifications of and deaths from tuberculosis during the year.

Dr. Mary Lowry, the maternity and child welfare medical officer, discusses the causes of high maternal mortality from childbirth. Arrangements have now been made to admit cases of puerperal fever to the isolation hospital. Of the nine deaths from other accidents, &c., of pregnancy, Dr. Lowry, after investigation, thinks that at least three might have been prevented had the woman been under skilled ante-natal supervision. There is as yet no definite coöperation between the ante-natal and V.D. clinics. The school medical service has not been reduced in scope, but the existing organisation is insufficient to deal with the requirements of the dental and minor ailments treatment clinics. The appointment of an additional dental surgeon is badly needed.

Stockport.

Dr. Arthur G. Jenner reports that the housing question is still unsatisfactory. The work of the various health centres—namely, tuberculosis, V.D., and child welfare—has progressed favourably during the year. It is doubtful if the maternity home (10 beds) will be large enough to meet the increasing demands made upon it.

SCHOOL MEDICAL SERVICE.

Cumberland.

AN instructive and outstanding feature of this report is the appendix containing a detailed survey of the county scheme for dealing with cripples. Up to the end of 1922 a total of 257 cases of crippling had been brought to the school medical officer's notice, and of these over 95 per cent. were cases of serious crippling ranging from simple club-foot to paralysis involving all four limbs. Interest in the scheme appears to have been thoroughly stimulated in the county, and names were submitted by members of the Education Committee, by the medical and nursing staff of the county, by the organisers of physical training, by private practitioners, teachers, and members of the general public. Dr. Kenneth Fraser, the deputy school medical officer, reports that the weakest point in the organisation is the discovery of early cases—that is, children under school age. With all these sources of information the register is not yet made up to date and new cases are coming to light every week. Owing chiefly to the fact that the numbers and length of stay would be an impossible tax on the local cottage hospitals, the cases are sent to hospitals outside the county—Shropshire Orthopædic Hospital and the Ethel Hedley Hospital, Calgarth Park, Windermere. Cases are classified according to urgency either on clinical grounds or on age.

After-care is a fundamental part of the scheme, and under this heading is included not only the after-treatment of hospital cases but the preliminary treatment by plaster, remedial treatment, &c., of cases before admission, in order to shorten the period of stay. Under it is also included the provision of appliances and re-education. The development of an adequate system of after-care has presented more difficulty than all the rest of the scheme put together and remains the greatest tax on the medical and nursing staff. At the beginning of 1921 a joint scheme of after-care with other counties was approved, and four after-care clinics were established at Carlisle, Maryport, and Whitehaven, and after some delay the first clinics were held in August, 1922, and have been eminently successful; altogether 82 children have attended, making 174 attendances.

Remedial treatment and re-education is a fundamental part of the treatment, and the seven clinics for such treatment have been established in the county. These are used by some patients as a preliminary to hospital treatment and serve to shorten the time spent in hospital, thus reducing the cost. They are, of course, most useful in preventing the further development of slighter deformities. It appears most unfortunate that all remedial treatment in the elementary schools and in a number of secondary schools of the county has ceased since December, 1922, owing to the so-called economy campaign. A few points are given at the end of the report for authorities contemplating a scheme for dealing with cripples, and Dr. Fraser lays emphasis on the necessity for careful organisation of after-care, with a person in charge who knows all about plaster and appliances work and something about re-education of muscles.

During the year 12,548 school medical inspections were made, and Dr. F. H. Morrison has followed out his practice of the previous year and has not resumed the weighing and measuring of children, and the services of three whole-time nurses have been dispensed with.

Soke of Peterborough.

Of the 317 secondary school-children examined, only one case of uncleanliness was recorded. Again Dr. Christopher Rolleston acknowledges his indebtedness to the school nurse. "I am every day, in every way and in every respect more and more indebted to Nurse Bean for her valuable services." In addition to attending at all medical inspections and reinspections, she has made 4990 examinations for cleanliness and paid 470 visits to homes on account of non-attendance from illness. She also paid 574 home visits for the purpose of arranging for treatment of physical defects. Dr. Rolleston, commenting on our lamentable lack of bathing facilities, recalls how grossly inefficient our arrangements for cleanliness are compared with the time of the Roman Empire. "Even small farmhouses near Pompeii were provided with bathrooms. Surely the freedom from certain forms of contagious disease in classic times depended on this wise expenditure of public and private funds." Dr. Rolleston's report is as usual most interesting and packed full of instructive suggestions.

MENTAL HOSPITALS SERVICE.

The annual report of *Croydon Mental Hospital*, Warlingham, records with some satisfaction a recovery rate for the year of 57 per cent. This institution, which was opened in 1903, was the first in England to be described as a mental hospital, and may, therefore, be said to have set an example to which some of the subsequent progress elsewhere is indebted. Its therapeutic resources resemble those of a general hospital, and importance is attached to the value of specialised methods of treatment. The hospital is at present overcrowded to the extent of 51 males and 39 females, and it seems possible that contracts with other institutions may be necessary in order to relieve this congestion. The post of pathologist and third assistant medical officer is vacant.

At the *Worcestershire Mental Hospital*, Barnsley Hall, Bromsgrove, the post of second assistant medical officer is vacant, and it appears that only one medical officer, in addition to the superintendent, is at present available for the care of about 730 patients. No explanation of the apparent failure to fill this vacancy appears in the report. No report of a Commissioner of the Board of Control appears in this issue.

Correspondence.

"Audi alteram partem."

HEART DISEASE IN EARLY LIFE.

To the Editor of The Lancet.

Sir,—Dr. G. Arbour Stephens's letter on the above subject in your issue of to-day's date deals with the great divergence of opinion as to the value of the salicylates in the treatment of the acute rheumatic state, which found expression at the recent meeting of the British Medical Association; and it urges the appointment of a commission to investigate the whole problem. I fear that, in view of this great divergence, the labours of such Commission would not bear much fruit, and this very largely because of the strange mental attitude (so it strikes me) of many doctors towards remedial treatment, especially by drugs. Thus Dr. Stephens uses the term "powerful poison" when speaking of the salicylates. Now the question of poison for every medicament is wholly a matter of dose, and, given careful dosage, surely the great body of medical opinion would pronounce unhesitatingly in favour of the salicylates as valuable remedies in acute rheumatism; or would anyone propose that we should revert to the use of the unaided alkalies, blisterings, &c., which our predecessors were so thankful to exchange for the salicylates?

One contributor to the B.M.A. discussion describes "the treatment of rheumatism by pharmacopœial doses of salicylates as only playing with a serious disease." I gather that what is meant is that we must go to the root of the matter and prevent rheumatism. The answer would be, "By all means this must be our endeavour"; but *meanwhile*, until we have reached that goal, and when faced by the attack, do we know of any other means of cutting short and mitigating the disease so effective as the salicylates? And is the alleviation of disease "playing" with it? Another holds that salicylate has not "diminished the incidence of carditis"—that is a statement very difficult of proof, but supposing it to be established, what then? Why then do not use it for that purpose be content with lowering and cutting short the fever and relieving the pain. If it be impossible to prevent the entry of the "strong man" upon the scene, we can at least mitigate the situation by disarming him in part.

Let us then use a drug for what it can do and not abuse it for that which it cannot compass; remembering always that there is but one rule in treatment—namely, to reach back into the morbid sequence of cause and effect *as far as we can and attack it there*; so doing we shall prevent or palliate, as the case may be, secundum artem.

I am, Sir, yours faithfully,
Harrington Sainsbury.

Wimpole-street, W., Sept. 1st, 1923.

DECAPSULATION OF THE KIDNEY IN ECLAMPSIA.

To the Editor of The Lancet.

Sir,—The growing experience that decapsulation of the kidney in eclampsia with anuria is a life-saving procedure—an example of which you quote and discuss in your issue of August 18th—calls for some comment and especially for this, that it presents the climax of the argument that eclampsia is simply the result of visceral disabilities determined by mechanical circulatory difficulties arising locally in pregnancy. It shows that the convulsions are not due to some specific toxin, or to the absence of some specific anti-body, as some have supposed, but result from failure of the excretory organs. Already the idea of a specific toxin in pregnancy (whether placental or endocrinal in origin), producing a toxæmia and eclampsia, is decadent—the results of the Dublin treatment indicate plainly enough that the pre-eclamptic toxæmia is simply a toxæmia due to an accumulation of "normal" waste products in the blood, that eclampsia is simply a uræmia. But the effect of decapsulation of the kidney indicates that the visceral disability (as far as the kidney is concerned) is caused by a circulatory difficulty arising within the kidney itself. Thus, in the case you have quoted, you refer to "the rapidity with which the operation had effect"; the effect, indeed, "was immediate." "Most recent authors," you say, "take the view that the chief effect lies in the mechanical relief of the renal tension," and, indeed, that "the French writer Pousson speaks of 'glaucoma of the kidney.'"

This last remark interests me greatly, for I have for long regarded the necrosis of the retinal cells in glaucoma as analogous with the necrosis of the renal cells in eclampsia, and have discussed the pathology of the former condition with certain ophthalmological friends. Just as in glaucoma the eyeball becomes "stony," so in eclamptic anuria is the kidney found "hard." It is plain that if the tension within the eyeball rises sufficiently the blood flow through the retinal capillaries will cease; and it is clear that if this obstruction persists, a necrosis of the retinal cells must occur. If the condition is recognised early and dealt with, the loss of vision (due to a functionless state of the cells) is restored; but if the condition persists, relief of the tension, even though it restore the blood flow through the retinal capillaries, cannot be hoped to give good functional results since the cells have become dead. The condition of the kidney in eclampsia is similar; in early stages (of anuria) the loss of function can be restored by re-establishing the flow of blood through the renal capillaries; but if the anuria persists several days (as in some reported), decapsulation of the kidney, even though it restore the blood flow through the kidney, cannot be expected to have the same result. Thus, decapsulation of the kidney should be done as soon as anuria is discovered, or as soon as it is found to persist in spite of all other measures.

How the increase of intra-ocular tension ending in glaucoma arises does not concern me; in the case of the kidney in eclampsia, there are two possible views. There is the view that the state of the kidney arises simply from the effect of a specific toxin or of the rise of normal waste products in the blood, and there is the view that it is due to mechanical circulatory difficulties induced within the organ by the pregnancy. It is difficult to understand, if the lesion affecting the renal cortical cells is due primarily to the effect of a poison, how decapsulation can affect the tissue. Were the renal lesion in eclampsia inflammatory in type, the case would be different, but it is non-inflammatory. There is a certain amount of round-celled infiltration, but Ludwig (1864)[1] showed that such occurred if one clamped the ureter even for one hour. He also showed that the kidney swells, that the uriniferous tubules become dilated, that the blood flow from the renal vein is reduced. Brodie (1914) showed that if a tate of diuresis is induced and the ureter clamped he kidney swells, becomes tense and hard, and "almost bloodless"; and that if the kidney be decapsulated and the ureter clamped the uriniferous ubules and Bowman's capsules become much more dilated, the whole organ becoming larger.[2] Clamping the ureter, obviously, must cause the uriniferous tubules to distend; and it is clear that the istension of these tubules, reacting with the capsule f the whole organ, must obstruct the blood flow hrough the renal capillaries.

Whilst in the past certain authors have thought that ureteral obstruction—e.g., at the pelvic brim—is a ause of eclampsia, we must believe that the dilatation f the cortical uriniferous tubules (such as Clifford White found in his cases[3]) is due to a mechanical difficulty arising within the kidney itself; that a block occurs, for instance, in the intermediary zone, causing a distension of the cortical uriniferous tubules which determines an occlusion of the blood capillaries about these tubules and the prevention of a blood flow through. This idea is supported by the occurrence of anuria as a result of rapid relief of urinary pressure in such cases as those of long-standing congenital phimosis and prostatic disease.[4] It is not very difficult to work out the process ending in such a block, at least in the latter conditions; but I must not encroach on your space to unfold this idea. It is obvious that on decapsulation of the kidney in such a state the intra-renal tension will be immediately reduced; that not only can the blood flow more readily through the kidney (in the absence of thrombosis), but that urine in cortical uriniferous tubules can more readily escape. That such a tension in eclamptic anuria exists is shown (as I have indicated) by the hardness of the kidneys found at operation (it is a state to which C. White expressly refers); and that such a mechanism is in play is demonstrated by the rapidity of the effect of the operation. The good results of decapsulation show that the degeneration and necrosis of the renal cells are not due to a primary thrombosis (the thrombosis, as I have previously urged, is secondary, not primary[5]); nor can we believe that cases of symmetrical necrosis of the renal cortex (an end-result of the condition we are considering) is due to an endarteritis to which it has been referred. The necrosis, presumably, is a late result (as is the retinal necrosis in glaucoma); and we must believe that had decapsulation been performed early enough in such cases restoration of function most probably would have resulted.

I am, Sir, yours faithfully,

R. H. PARAMORE, F.R.C.S. Eng.

Brook-street, W., August 23rd, 1923.

ACCIDENTAL VACCINIA.

To the Editor of THE LANCET.

SIR,—In view of the prevalence of vaccination it may be of interest to refer to an incident which occurred recently in my own practice. On the evening of July 24th a woman visitor from Birmingham consulted me for an "insect bite" on her right upper eyelid. She stated that the swelling had begun to appear on the morning of the 23rd, but evidently it had spread, for when I saw her she was quite featureless, while the puffiness of the lids was so pronounced that she could not see out of her right eye. In the centre of the upper lid was a scab, but it was not until this scab had been removed by bathing with warm hydrogen peroxide solution that I was able to obtain a clear view of the underlying cause. Then there appeared a clear vesicle rather larger than a sixpence deeply embedded in the tissues, and with a circular depression in the centre having all the appearances of a vaccination mark prior to the development of the pustular stage on the sixth or seventh day following inoculation of the virus. This led me to make further inquiries, and thus I came into possession of some quite useful information. Briefly the sequence of events was as follows:—

July 6th: Baby vaccinated, arm left uncovered.

17th: Baby scratched his mother on upper lid; the mark left by his finger-nails was clearly visible on the following day.

23rd: Lid began to swell up.

24th: A fully-formed vesicle was apparent in that situation, and developed after the manner of a cow-pox vesicle.

31st: The vesicle had shrivelled up, but the scab remained adherent while showing signs of separating at the margin. All traces of the swelling had gone.

It is probable that I should not have recognised the condition had it not been for a similar experience which befell me in the out-patient department of the

Westminster Hospital in the spring of 1906. One day a woman presented herself with an angry-looking pustule on the cheek, which I at first mistook for a malignant pustule, until my mind was set at rest by the surgeon in charge of out-patients inquiring all about the health of some infant of whose existence he seemed to be perfectly well aware, although he had not, so far as I could tell, ever been informed of its arrival.

Probably on account of the rarity of vaccination on parts of the body other than the arms and legs, no mention is ever made of the possibility of this condition being mistaken for that of anthrax, yet the resemblance is very close when, as in the case just mentioned, there is an outer ring of vesicles, and a *dark* scab forms from admixture with blood. The history is the most important thing, and next to that the presence or absence of severe constitutional disturbance. Even so, it is as well to bear in mind that vaccinia is sometimes severe, and that not every individual infected with anthrax is doomed.

I am, Sir, yours faithfully,

Bournemouth, August 30th, 1923. J. Stanley Avery.

THE FORAMEN OF MAGENDIE.

To the Editor of The Lancet.

Sir,—May I remind Prof. Wood Jones that Sir John Bland-Sutton's discovery of the non-existence of Magendie's foramen has been confirmed by F. Coupin, who shows, in addition, that the two lateral foramina of Luschka are also artefacts. The roof of the fourth ventricle is extremely fragile, and is very easily torn in dissections or in preparation of microscopical sections. Coupin found that all these three foramina are absent in the mouse, rat, guinea-pig, kitten, and young rabbit; and in his second paper he found the same thing in scyllium canicula, torpedo, carassius, and rana temporaria. In none of these animal forms is there any direct communication between the cavity of the fourth ventricle and the subarachnoid spaces. His papers are in the "Comptes Rendus de la Société de Biologie," (*a*) 1920, lxxxiii., p. 954, and (*b*) 1921, lxxxiv., p. 913.

I am, Sir, yours faithfully,

London, N.W., August 31st, 1923. Leonard J. Kidd.

THE STATUS OF PATHOLOGY.

To the Editor of The Lancet.

Sir,—The science of pathology is a branch of biology, but, while all other branches of biology are recognised as sciences by our universities, no university recognises pathology as such, nor is the Pathological Society regarded as one of the scientific societies. Pathology is rather regarded with contempt as a branch of medicine which any medical man is competent to teach. Hence we sometimes find that important posts in pathology are filled by the appointment of men who have had no experience in the subject, while those who have spent years in junior posts are passed over. We also find in some universities that the pathological department is run on commercial, rather than on scientific, lines, and it is the only department to be exploited in this manner.

Will not one of our universities take the initiative in raising the status of pathology—

1. By instituting a chair of general pathology.
2. By recognising general pathology as a subject for degrees in the faculty of science.
3. By establishing a course of training for pathologists of a standard equivalent to that of the honours courses in other branches of science.
4. By imposing on the staff of the pathological department the same restrictions as to outside work as are imposed on the staffs of other departments.

I quite recognise that there may be a difficulty in recognising pathology as a subject for science degrees, because, owing to the nature of the subject, the degree would, almost of necessity, have to be a post-graduate degree. If these difficulties are held to be insuperable a diploma might be instituted.

I may say that it is not only the universities which regard pathology with contempt. The medical profession itself regards the pathologist as an inferior order of being to whom the rules of medical etiquette do not apply. What an outcry there would be if the universities carried on clinical practice by means of their professors and lecturers in clinical subjects as they now carry on pathological diagnosis by means of their pathological staffs!

I am, Sir, yours faithfully,

Manchester, Sept. 1st. Charles Powell White.

LONDON PANEL: POST-GRADUATE COURSES.

To the Editor of The Lancet.

Sir,—Further courses of post-graduate instruction have been arranged by the London Panel Committee with the assistance of the authorities of Guy's Hospital, to take place in the coming autumn. The courses will be held in general medicine, midwifery and gynæcology, and in the diseases of the ear, nose, and throat. Each course will consist of ten lectures of one hour's duration and will probably commence on Sept. 20th. The classes will be held simultaneously on Thursday afternoons at 4 p.m. The fee for each course will be £3 3*s.*, payable in advance to me, and cards of admission will be issued. There will be special instruction in the treatment of diabetes by insulin and in the treatment of tuberculosis by Dreyer's diaplyte vaccines. Early application for inclusion in either of the above courses should be made as the numbers admitted will be limited.—I am, Sir, yours faithfully,

Robt. J. Farman,
Secretary, Panel Committee for the County of London.
Staple House, 51, Chancery-lane, W.C. 2,
August 29th, 1923.

Obituary.

ERNEST FRANCIS BASHFORD, O.B.E.,
M.D., Ch.B. Edin.

Ernest Francis Bashford died suddenly of heart failure on August 23rd, at Manderscheid, Eifel, Germany, at the early age of 49. He was born at Bowdon, Cheshire, in 1873, educated at George Heriot's Hospital School and Edinburgh University, graduating M.B., Ch.B. in 1899 and M.D. 1902, after a distinguished academical career. He travelled to Germany as holder of the McCosh Scholarship of Edinburgh University, and later of a Grocers' Scholarship, and studied under the late Prof. Ehrlich at Frankfort. Later he was assistant to Prof. Liebreich in the Pharmacological Institute in Berlin. He returned to Edinburgh in 1902 as assistant to Sir T. R. Fraser, and while there published his well-known monograph on the pharmacological antagonism of atropine and morphine.

In 1902 Bashford was appointed director of the newly founded Cancer Research Fund, a position which he held till 1914, when he resigned through ill-health. During these 12 years he held a prominent position in cancer research in this country and on the Continent and built up the organisation of the Imperial Cancer Research Fund as an experimental research institute. His work at the Imperial Cancer Research Fund will best be remembered by the numerous contributions on the zoological and ethnological distribution of cancer, national and hospital statistics, the phenomena of transplantability of animal tumours and the induced resistance to them. Into the controversies which raged around these topics he threw himself with enthusiastic energy.

Dr. Bashford served in the R.A.M.C. from 1915 till the end of the war and afterwards in the Army of Occupation till some months before his death. He leaves a widow and one daughter, to whom the greatest sympathy will be extended.

EDWARD ALEXANDER WHITE, M.D., M.CH., L.M. R.U.I.

Dr. E. A. White, the oldest practitioner in the Isle of Thanet, died at Margate on July 18th, aged 70 years. He was educated at Queen's College, Belfast, and qualified M.D., M.Ch., and L.M. in 1877. After practising for a short time in London, he entered into partnership at Margate with the late Mr. W. H. Thornton and the late Mr. W. Knight Treves, nearly 50 years ago. For many years he held the appointment of visiting physician to the Isle of Thanet Isolation Hospital, a post which he gave up a few months ago owing to failing health. On his resignation he was appointed consulting physician to the hospital. In his earlier years in Margate he was district medical officer, and held numerous club appointments before the National Insurance Act was passed. He was also surgeon to the local battery of the Cinque Artillery Volunteers, resigning his commission when the Territorial system was introduced. Ten years before his death White underwent a grave operation and afterwards gradually relinquished active practice, though he attended some of his old patients until a few weeks before his death from cerebral hæmorrhage. His last public appearance was at the dedication of the "White" bed, which he endowed at the Margate Cottage Hospital in memory of his second son, who gave his life on the shores of Gallipoli. Edward White was greatly loved by his patients, and though his activities had been greatly limited by his loss of health, those who knew him in his prime will always cherish the memory of one who was a kind and generous friend as well as a beloved physician.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comrs. W. H. Edgar to *Cyclops*; F. E. Bolton to *Victory*, for R.N. Hospital, Haslar, and as specialist in diseases of the nose, ear, and throat, temp.; H. M. Late Temp. Surg. (R.N.) J. E. Purves transferred to permanent list of R.N.V.R. as Surg.-Lt. and attached to the Scottish Division, List II.

The following late temp. Dental Surgeons have been transferred to the permanent list as Surg.-Lts. (D.): T. P. Cooper (attached to London Division, List 11); G. W. E. Holloway (attached to London Division, List 11); A. G. D. Pridham (attached to Bristol Division, List 11); D. C. Lamond (attached to Scottish Division, List 11); E. G. Parkinson (attached to London Division, List 11); G. R. D. Hankinson (attached to Sussex Division, List 11); and A. C. Bloomer (attached to Tyne Division, List 11).

ROYAL ARMY MEDICAL CORPS.

Maj. W. W. Browne, O.B.E., relinquishes the temp. rank of Lt.-Col.

Capt. H. D. Lane, M.C., retires receiving a gratuity and s granted the rank of Maj.

Lt.-Col. H. F. Shea, D.S.O., is restd. to the estabt.

Capt. P. Carney, M.C., retires receiving a gratuity and s granted the rank of Maj.

TERRITORIAL ARMY.

Capt. F. B. Chavasse, M.C. (late R.A.M.C.), to be Capt.

INDIAN MEDICAL SERVICE.

Lt.-Col. E. L. Perry, D.S.O., to be Col.

The King has approved the retirement of the following officers: Col. R. G. Turner, C.M.G., D.S.O.; Sen. Asst. Surg., with rank of Maj., E. J. Murphy.

The King has approved the relinquishment of his temp. commn. by the following officer: Capt. Gnanadickam Ira Benjamin, and is permitted to retain the rank of Capt.

ROYAL AIR FORCE.

Flying Officer J. D. Leahy, M.C., is granted a permanent commission.

The following appointments in the Royal Air Force are notified: Flight-Lt. (Medical) A. F. Rook to R.A.F. Central Hospital, Finchley; Flying Officer G. Clark to R.A.F. Hospital, Cranwell.

Medical News.

CIVIL SERVICE OFFICERS: REDUCTION OF BONUS.—A circular, No. 439, has been issued to local authorities by the Ministry of Health setting forth the new scale of reduction of bonuses payable to permanent civil servants. On wages and salaries not exceeding £500 per annum the bonus will be reduced from Sept. 1st, 1923, by a further 1–26th (making 11–26th in all since September, 1921). This scale is based on an average cost of living figure of 75. In the case of salaries over £500 a year a corresponding reduction of bonus will be made, and the bonus will still be subject to the special percentage deductions specified in paragraph 2 of the statement appended to the circular No. 233 of August 30th, 1921, subject to the following provisos: (1) That ordinary remuneration above £500 a year shall not involve lower total remuneration than ordinary remuneration of £500 a year. (2) That the higher percentage deductions specified in the statement take effect at the exact £700, £800, &c., of ordinary remuneration, and the total remuneration for those points constitute a maximum which may not be exceeded in the case of remuneration just below, for which the percentage deduction is lower. (3) That in no case shall bonus be payable at a rate which will raise the total remuneration above £2000 per annum. In so far as insurability under the National Health and Unemployment Insurance Acts is determined by rate of remuneration, Civil Service officers (employed otherwise than by way of manual labour and in receipt of bonus on the Civil Service scale) whose salary plus the reduced bonus does not exceed £250 per annum should thus be treated as insurable from Sept. 1st.

THE "FIELD" DISTEMPER FUND.—The buildings, for which the Fund has authorised the payment of £3540, are shortly to be erected on a portion of the ground on the experimental farm of the Medical Research Council at Mill Hill. The portion of the ground reserved for this investigation will be surrounded by an unclimbable fence forming a compound in which will be situated the kennels and the bungalow for the kennel maids; while in the wall of the compound will be placed a building to be used as a cleansing room, which will afford the only means of egress or ingress into the compound. There will be also in the wall of the compound another building to be used as a store and for preparing the food for the dogs, which will be passed through a small hatch and carried away in a sterile vessel. Coals will be carried into the compound through a similar hatch. The cleansing room consists of an outer chamber, a bathroom, and an inner chamber. All persons who have to enter the compound, as well as the kennel maids, must pass through this building; on entering they have to leave their outer garments in the first chamber, have a bath, and put on sterilised clothes in the inner chamber before entering the compound. The bungalow for the kennel maids is already built, and contains good sleeping and sitting-room accommodation, and a good cooking range. The kennels are arranged eight on each side of a corridor covered with corrugated iron and floored with cement; there is an open space between each set of two kennels, so that at any time two or four can be isolated. Each kennel is 8 ft. square, with a yard 36 ft. by 8 ft., and these yards are divided from each other by 6 ft. compo. wood divisions. The floors of the kennels will be of asphalt, and the yards will be floored with ashes, so that in the case of infection they can be replaced, limed, and disinfected. The roofs of the kennels will be made of ruberoid. The only other entrance into the compound will be the gate for the admittance of the dogs; the key of this gate will be kept by Mr. J. B. Buxton, F.R.C.V.S., who is in charge of the establishment. The hospital will not be situated within this compound, but at some distance away. It will be so constructed that if one side became infected that side could be completely shut off from the other side, and the experimental work could still be carried on in the uninfected portion. The hospital will be made fly-proof. It is further announced that an American Distemper Committee—several member of which have been coöpted on the British Council—has been formed. Sir William Leishman, F.R.S., having resigned from the Special Research Committee owing to his recent appointment as Director-General, Army Medical Services, Dr. C. J. Martin, F.R.S., has been appointed chairman of this committee.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE, SPECIAL COURSE IN INFANTS' DISEASES, at the Infants Hospital, Vincent-square, Westminster, S.W.

Monday, Sept. 10th.—2–3.30 P.M., Dr. William Robinson: Lymphatic Diathesis. 4.30–6 P.M., Dr. Eric Pritchard: Demonstration: Uses of Dried Milk.

Tuesday.—2–3.30 P.M., Dr. Eric Pritchard: Acidosis in Infancy. 4.30–6 P.M., Dr. Helen Mackay: Nutritional Diseases with special reference to Rickets and Scurvy.

Wednesday.—2.30–3.30 P.M., Dr. Helen Mackay: Cases illustrative of Nutritional Disorders in the Wards and Out-patient Department. 4.30–6 P.M., Dr. Donald Paterson: Blood Conditions in Infancy; Demonstration in Research Laboratory.

Thursday.—2–3.30 P.M., Dr. Donald Paterson: Nerve Cases in the Wards and Out-patient Department. 4.30–6 P.M., Dr. Eric Pritchard: Demonstration in Milk Laboratory; Modification and Preservation of Milk.

Friday.—2.30–3.30 P.M., Dr. Eric Pritchard: Round Table Consultation. Special Cases for Diagnosis. 4.30–6 P.M., Mr. Tyrrell Gray: Lecture: Pyloric Stenosis. Demonstration and operation if possible.

Saturday.—Expedition by motor charabanc to Nursery Training School, Garden Suburb, Hampstead, and Sunshine House (Home for Blind Babies), Chorley Wood, leaving Royal Society of Medicine, 1, Wimpole-street, at 2.30 P.M.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

Monday, Sept. 10th.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

Tuesday.—10.30 A.M., Dr. Paterson: Medical Wards. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Wednesday.—2 P.M., Mr. Gibb: Eye Department. 3 P.M., Dr. Pernet: Skin Department.

Thursday —12 noon, Mr Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Department. 3 P.M., Dr. Scott Pinchin: Medical Out-patients.

Friday.—10 A.M., Mr. Dudley Buxton: Dental Department. 2 P.M., Dr. Burrell: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Saturday.—10 A.M., Dr. Paterson: Medical Diseases of Children.

Daily, 10 A.M. to 6 P.M. Saturdays 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

Appointments.

Cardon, A. G., M.B., B.Ch., has been appointed Assistant School Medical Officer, Sheffield.

MacKenzie, Ella, M.B., Ch.B. Edin., D.P.H., Assistant Medical Officer of Health of Blackburn.

Manchester Royal Infirmary: Witts, L. J., M.B., Ch.B. Manch.; Coleman, A., M.B., Ch.B. Manch.; Barlow, A., M.B., Ch.B. Manch., House Physicians. Parkes, M., M.B., Ch.B. Manch.; Fouldes, E. J., M.B., Ch.B. Manch.; Latham, T., M.B., Ch.B. Manch.; Bowman, B., M.B., Ch.B. Manch.; Fleming, W. A. J., M.B., Ch.B. Manch., House Surgeons. Sharp, C. J., M.B., Ch.B. Manch., House Surgeon to Special Departments. Bryce, A. G., M.D. Manch., F.R.C.S., Surgical Registrar.

Vacancies.

For further information refer to the advertisement columns.

Aylesbury, Royal Bucks Hospital.—R.M.O. £200.

Bristol Royal Infirmary.—H.S. to Ear, Nose, and Throat Dept. £120.

Carnegie Dunfermline Trust, Abbot-street, Dunfermline.—Asst. M.O. £550.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Two Asst. Surgs. and Three Registrars.

Chester Royal Infirmary.—Asst. H.S. £150.

Dreadnought Hospital, Greenwich.—H.S. and H.P. Each £150.

East African Medical Service.—M.O. £600.

Exeter, Royal Devon and Exeter Hospital.—Asst. H.S. £150.

Glasgow District Mental Hospital, Gartloch.—Jun. Asst. M.O. £350.

Halifax Royal Infirmary.—Third H.S. £150.

Leicester City.—Asst. Tuberculosis O. £550.

London County Mental Hospital Service.—Seventh Asst. M.O. £432.

Manchester, Ancoats Hospital.—Res. M.O. £200.

Newcastle-upon-Tyne, Hospital for Sick Children.—Jun. R.M.O. £140.

Newcastle-upon-Tyne Royal Victoria Infirmary.—H.P.'s and H.S.'s, residents. £50.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. H.S. £100.

Redhill, Surrey, Royal Earlswood Institution.—Jun. Asst. M.O. £250.

Royal Chest Hospital, City-road, E.C.—R.M.O. £200. Also H.P. £120.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—H.S. £150.

Royal Naval Medical Service.—Surgeon-Lieutenants.

Royal Northern Hospital, Holloway, N.—H.S. £100. M.O. £150.

Saint Pancras Dispensary, 39, Oakley-square, N.W.—Hon. S.

St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—H.S. £75.

Salford Royal Hospital.—H.P. and H.S. £200. Also Cas. H.S. £150.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. £100.

West African Medical Service.—M.O. £660.

West Bromwich and District Hospital.—Res. Asst. H.S. £180.

West London Hospital, Hammersmith-road, W.—H.P.; also two H.S.'s. £100.

Winchester, Royal Hampshire County Hospital.—H.P. £150.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Stowmarket, Suffolk; Kirkwall, Orkney; Maidenhead, Berks.

Births, Marriages, and Deaths.

BIRTHS.

Blackley.—On August 31st, at West Highwood, Walton-le-Dale, near Preston, the wife of F. J. Blackley, M.D., of a daughter.

Butler.—On Sept. 1st, at "Brookfields," West Kirby, the wife of G. Guy Butler, M.D., B.Ch., of Dar-es-Salaam, Tanganyika Territory, of a son.

Craig.—On August 28th, at Culmington-road, Ealing, W., to Eileen, the wife of Squadron-Leader E. W. Craig, M.B., B.Ch., R.A.F.—a daughter.

Murray.—On August 28th, at Osman House, Fortis Green, N., the wife of James R. Murray, M.D. Aberd., of a daughter.

MARRIAGES.

Bethune—Penney.—On August 13th, in London, Henry Norman Bethune, F.R.C.S. Edin., M.B. Toronto, to Frances Eleanor, only daughter of the late José Campbell Penney and Mrs. Campbell Penney, of Edinburgh.

Harvey—Millard.—On August 25th, at Marylebone, Dr. William Harvey, to Florence Elizabeth Millard.

O'Mullane—Cowie.—On August 30th, at the Church of Our Lady of Grace, Charlton, Jerome John O'Mullane, M.B., B.Ch., B.A.O. N.U.I., to Annette Isabella, eldest daughter of Dr. and Mrs. Cowie, Charlton, S.E.

Turtle—Burton.—On August 30th, at the Parish Church of S. Mary, Stansted, Essex, James Turtle, M.R.C.S., L.R.C.P. Lond., to Elaine Clara Constance, youngest daughter of Mr. and Mrs. Ernest L. Burton, of Stansted, Essex.

DEATHS.

Carter.—On August 29th, suddenly, at The Lawn, Lord-street West, Southport, Weldon Cragg Carter, M.D. Lond., M.R.C.S., L.R.C.P. Lond.

Hart.—On Sept. 1st, George Simpson Hart, M.D., of Measham, Burton-on-Trent, aged 55.

Taylor.—From heart failure after heatstroke, Alan Everley Taylor, M.A., B.M., Ch.B. Oxf., Surgeon City Line, formerly Resident Ophthalmic Officer, Leeds Infirmary, and Captain, R.A.M.C., 1914–1919.

Webster.—On August 30th, at his residence, The Avenue, West Ealing, W., Ridley Manning Webster, M.R.C.S. Eng., L.R.C.P. Edin., in his 77th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

PUBLIC HEALTH IN ASSAM.

THE report on Public Health in Assam for 1921[1] deals only with the population of the plains districts of the province, the population of which districts is stated as 6,854,367, being an increase of 802,860 over that of 1911. (The population of the whole province (1921) is stated as 7,606,230 in Whitaker's Almanack, 1923.) The total births registered numbered 203,153, giving a ratio of 29·63 per 1000, as compared with 32·19 in 1915–19 and 31·53 in 1920; but this latter ratio was calculated on the population of the previous census, and if the 1921 ratio were calculated on that basis it would be 33·57—that is, there was really an increase in the births. In the other provinces of India the ratio varied from 27·05 in Madras to 41·50 in the Punjab (Bengal statistics are not available). In the districts of Assam the birth-rate ranged from 24·16 in Lakhimpur and 25·08 in Sibsagar to 32·30 in Sylhet and 33·58 in Goalpara. The death-rate was 26·48, against 36·17, the quinquennial average, and 27·77, the average for the pre-influenza quinquennium, 1913–17. This indicates that the public health has recovered from the after-effects of that visitation. In Sibsagar district the mortality was only 20·08; in Goalpara it was 34·02 per 1000. Cholera caused 12,829 deaths (1·87 per 1000, compared with 2·46, the decennial average). Among the rural districts Goalpara, in the Assam valley, suffered most, with a mortality of 3·66 per 1000; and after this Cachar, in the Surma valley (2·97). The largest number of deaths (5885) occurred in the populous Sylhet district (2·35 per 1000). In the towns, Gauripur (7·42), Habiganj (5·57). and Karimganj (5·27) had the highest ratios; the water-supplies in these places are unprotected and their sanitary arrangements primitive. The small-pox mortality was 0·40 per 1000, compared with 0·47 in the decennium. In the Darrang district the ratio was 2·38; the epidemic was confined to certain villages in the Mangaldai subdivision, where vaccination had been neglected. The total fever death-rate was 15·7 per 1000, as compared with 18·57 in 1920, 17·18 in the decennium 1911–20, and 14·91 in the pre-influenza decennium, 1908–17. Good results have followed on the carrying out of the Lumding anti-malarial scheme, the attacks per head per annum having been nearly halved, and the splenic index in the bazaars very largely reduced; similar satisfactory results have been reported at Pasighat. The mortality from kala-azar (2987 deaths) was somewhat higher than in 1920 (2798), and, indeed, was higher than in any previous year; but this was probably "to some extent due to an increased attention to the disease leading to a subtraction from the fever deaths and addition to the kala-azar deaths." Forty-three assistant and sub-assistant surgeons were employed on special duty, and 12 indoor hospitals, with a total of 226 beds, were open for reception of patients, in addition to accommodation in other hospitals and treatment at dispensaries; the total patients numbered 15,880. Lieut.-Colonel McCombie Young, I.M.S., Director of Public Health for the province, who presents this report, notes that "it is indeed a stimulating sight to see the troops of patients, mostly attending our dispensaries and hospitals, and voluntarily and cheerfully undergoing a treatment in which their chances of recovery are now equal to what were formerly the chances of almost certain death"; and "ventures the opinion that Government money has rarely been spent to better purpose in the saving of life and health."

The mortality from dysentery and diarrhœa was 1·68, compared with 2·37 per 1000 in the decennium 1911–20, varying from 0·33 in Goalpara district to 3·23 in Lakhimpur. There was an improvement in every district except Kamrup, where the ratio was 1·00, compared with 0·92 in the decennium. In the tea gardens the ratio was 5·25, varying from 2·30 in Kamrup to 7·21 in Lakhimpur. "Speaking generally, there is little doubt that something like half the mortality and inefficiency among the labour populations of tea estates is due to bowel complaints, and much of it is preventable by the introduction of modern methods of refuse disposal; as lack of conservancy, hookworm infestation, and bowel diseases, work together in a vicious circle to maintain the high mortality rates in question." There has been a period of financial depression in the tea industry, but expenditure in this direction, by leading to increased health and efficiency, will undoubtedly be a true economy in the end. In Sylhet district "the conservancy system suffered serious detriment as the result of a turn of municipal politics, whereby, in the name of retrenchment, nightsoil carts and animal traction were replaced by hand removal, with results that were to be expected. . . . The incident raises the question as to whether more control should not be exercised by Government over the results of the activities of municipal politicians when these are likely to endanger the health of the community." We suggest that "the answer is in the affirmative." Dibrugarh, in the Assam valley, is the only considerable town in the province now unprovided with a filtered water supply, having refused the offer when other towns were being equipped, and being still dependent on unprotected wells. No action appears to be contemplated. A sanitary inspector, now styled "health officer," has been appointed for each of the four towns of Habiganj, Sunamganj, Karimganj, and Sibsagar, as well as four rural health officers for as many local boards. It is too soon to offer any optimistic forecast as to the improvements in rural sanitation that may result, but "one ventures to hope that, when the present financial stringency disappears, it will be found possible to provide every local board in the plains districts with a health officer."

The Jail Population.

The jail population in this province averaged 2656 in 1921, as compared with 2514 in 1920. The convicts averaged 2314, an increase of 155 over the previous year, "mainly attributable to the non-coöperation movement; of the total number (4608) admitted, 1018 were for offences against the public tranquillity. There was a marked decrease in the female prisoners admitted, 78 as compared with 138 in the previous year; but there was an increase in the numbers of those who were able to read and write (5·27 per cent.), or to read only (0·41 per cent.), compared with 1·64 and 0·02 per cent. respectively in 1920; the increase was due to the non-coöperation prisoners, who mostly belonged to the educated class. "It is remarkable that prison offences are declining steadily, while the jail population is gradually on the increase"; the total offences numbered 2591, against 3030 in 1920 and 3688 in 1919. It might be suggested that this is because the standard of education has been higher. As regards the health of the prisoners, the admissions to hospital were 909·8, the average daily sick 39·5, and the mortality 35·38 per 1000; the corresponding ratios for the preceding year were 758·09, 35·77 and 25·06. It is noteworthy that the jail death-rate, which from 1915 to 1919 had been very considerably lower than that of the population of the province generally, in 1920 nearly equalled the provincial rate (25·06 compared with 28·98 per 1000), and in 1921 rose to 35·38, while the provincial rate fell to 26·48. The main cause of death was influenza, which "instead of passing in epidemic form through the jails, has been almost constantly present." Vaccine, either as prophylactic or curative, has not been successful. As compared with the jail statistics of other Indian provinces, the total Assam mortality (35·38 per 1000) was only exceeded by that in the Central Provinces (35·53); in the adjoining province of Bengal it was only 16 per 1000. By an obvious, but unfortunate, typographical error, the table on p. lxvii shows the deaths among convicted prisoners in the various jails of the province from diarrhœa as having been in a ratio of 941 per 1000.

Vaccination.

In the report on Vaccination for the three years, April, 1920, to March, 1923, it is stated that the total number of operations during this period amounted to 1,162,931, showing an increase of 77,558 on the preceding triennium. In the three years now reported on, however, the numbers were 418,936, 367,548 and 376,447, showing a considerable decrease in 1921–22, and only a very slight recovery in 1922–23; the decrease was due to the non-coöperation movement. The small-pox mortality in the province has naturally increased during the period: in 1919–20 it was 0·20 per 1000; in 1920–21, 0·24; in 1921–22, 0·35; and in 1922–23, 0·38. Where vaccination is performed the results are very satisfactory, the success ratio having been 94·91 per cent. for primary operations during the triennium, and 62·2 for revaccinations. The lymph is prepared at the Shillong dépôt, and is issued after having been kept three months in cold storage. All districts showed an increase in the number of operations, compared with the previous triennium, except Manipur State, where there was a decrease of 50,683, Kamrup (26,187), and Cachar (5096). The average number of operations per vaccinator in 1922–23 was 1108; in the Garo Hills district the average was 1652.

Mental Treatment.

In the Assam provincial lunatic asylum at Tezpur there were confined 413 patients at the end of 1920, and 105 were admitted during the year 1921. The daily average strength was 427, compared with 399 in the year preceding; 51 patients were discharged, of whom 49 were cured, and two "mentally improved." The admissions to hospital numbered 126, of which 24 were for dysentery and 15 for diarrhœa, as compared with 16 and 12 in the previous year. Colonel J. Garvie, I.M.S., Inspector-General of Civil Hospitals, who forwards this report, emphasises the dependence of dysentery on the filthy condition of the patients and site overcrowding. Of the new admissions to the asylum, 29 per cent. were in bad health and 45·3 with indifferent health on arrival. A hospital ward for dysentery cases is urgently required.

---

HEALTH CONDITIONS IN CYPRUS.

A REPORT for the year 1922 has been received at the Colonial Office on the affairs of this island, situated in the eastern Mediterranean. The island is about 140 miles in greatest length from east to west, and about 40 miles in greatest breadth from north to south. The population, as shown in the census return taken in 1921, was 310,709. Public health in 1922, except for a severe epidemic of measles throughout the island, was again good, the stringent quarantine regulations in force proving effectual in preventing the introduction into the country of plague, typhus, and other virulent diseases prevalent in most neighbouring countries of the Levant and the Near East. This complete immunity is the more satisfactory when it is considered that several thousands of refugees, many of the poorest class, found asylum in Cyprus from Smyrna, Cilicia, and Asia Minor. An outbreak of small-pox, which was brought into the island by Armenian refugees from Mersina, in Cilicia, at the beginning of the year, was immediately detected and suppressed; 86 cases in all were recorded, of which 16 were fatal. Some 50,000 vaccinations were carried out. Cyprus continued to be free from rabies, and the regulations prohibiting the importation of dogs from any destination were again strictly enforced during the year. The prevailing diseases were, as in 1921, those of the digestive and respiratory system, influenza, diseases of the skin, rheumatism, malaria, and enteric fever. The anti-malaria campaign was, as usual, conducted under the supervision of the medical officer of health, though the spleen-rate, which is regarded as the index of malaria in a country, showed a tendency to rise, a circumstance attributed to the rains which fell exceptionally late in the spring and early summer of 1920 and 1921. The births registered were equivalent to 28·0 per 1000, and the deaths to 29·0 per 1000 of the population, as compared with 26·6 and 19·8 respectively in 1921. The marked increase in the death-rate is attributed to the severe epidemic of measles already referred to, which caused a greatly increased mortality among children and infants, the death-rate for the latter under 1 year being 167·6 per 1000, as compared with 130·4 in 1921. The climatic conditions generally during the prolonged summer were exceptionally exhausting, and the great heat and excessive dryness proved fatal in many cases of old age and chronic sickness. There were Government-maintained or aided hospitals in operation in the six principal towns, and 16 rural medical officers worked among the village population. The new hospital at Limasol has been opened and is now in operation. Over 1300 patients were admitted to the Central Hospital at Nicosia, which is fitted with 56 beds, and the out-patients treated numbered rather more than 8000. Some 150 surgical operations were performed. More than 18,500 persons received relief at the rural dispensaries. The number of lepers detained in the Leper Farm at the close of 1922 was the lowest on record—i.e., 69, as against 90 in 1916, and 102 in 1909. The admissions to the Farm were only five, as against nine in the two previous years, and there were nine deaths, all of which were advanced cases of the disease. Some of the inmates were treated internally with chaulmoogra oil with good results, though no actual cure can yet be reported. The beneficial effect of segregation is beginning to tell, and leprosy in Cyprus is now well in hand, hopes being entertained that it may be possible entirely to eradicate it from the island. The number of children at the close of the year in the home for the healthy children of lepers was 10, all of whom remained free from any sign of the disease. The climate of Cyprus is, generally speaking, temperate and healthy, though the excessive heat of the plains during the summer is trying to Europeans. The heat is, however, dry, except on the coast, while the winters are cold and invigorating. The absolute mean temperature for the year at Nicosia was 66·90° F., as against the average of 65·80° for the last 15 years. The mean maximum temperature was 78·60° F., and the mean minimum 55·20° F. The rainfall for the last ten years has averaged 20·09 inches per annum; in 1922 the mean for the whole island was 18·41 inches, as against 22·44 in 1921. The experience of the last decade would seem to show that the climate of Cyprus tends slowly but surely to change. While the excessive heat in the plains still prevails during midsummer the winters are colder, and late rains not infrequently fall, even up to the months of May and June, a circumstance attributed principally to the conservation and extension of the island's forests.

THE EARLY DAYS OF LETTSOM.

AN account [1] compiled from letters, diaries, and minute books of the Quaker settlement (1741–1786) in Tortola, one of the Virgin Islands, is of medical interest because in Little Jost Van Dykes, an islet off Tortola, there was born in 1744 John Coakley Lettsom. His birth was remarkable in that he is said to have been one of the seventh pair of boy twins born to his mother, of which family he and his brother Edward were the sole survivors. His father was Edward Lettsom, who owned this and sundry other islets together with a cotton plantation on Tortola. Edward Lettsom died in 1754 and his widow married again. There is an amusing entry on p. 35 giving "the Widow Lettsom's" reply to chidings for not attending meetings: "Frinds slited her and set her at noat and she being left destitute from human help not a negro to assist her. Meetings being at a distance and thinking it hard to be slited by Friends in her distress, had quit attending meeting." Slavery was at this time not considered inconsistent with the profession of Quakerism or, indeed, of any other body of Christians, but it is notable that John Coakley Lettsom, who had been sent to England to be educated at the age of 6—i.e., in 1750—returned to Tortola more or less qualified as a medical man in 1767, when his first action was to free his slaves. The book gives a most interesting picture of a phase of eighteenth-century society very little known to most people.

SUSPECTED CASES OF PLAGUE AND CHOLERA.

IN a circular (No. 437) addressed to port and riparian sanitary authorities it is stated that in several recent instances the Minister of Health has not been informed promptly of the occurrence of suspected cases of plague on ships arriving in ports in this country, and there has also been delay in forwarding to the Ministry for bacteriological investigation material obtained from such cases. The Minister reminds sanitary authorities that under the International Sanitary Convention of Paris, 1911/12, the Governments of all countries participating in the Convention must immediately be notified by H.M. Government of the occurrence of any case of plague or cholera in this country, and it is therefore of the utmost importance that every suspected case of plague or cholera should at once be reported to him. Material from such cases, if obtainable, or from rats suspected to be suffering from plague, should, as soon as practicable, be forwarded to the Ministry for bacteriological investigation. Directions for the taking and transmission of such material have been forwarded to the port medical officers of health.

CODE WORDS FOR MEDICAL TELEGRAMS.

To the Editor of THE LANCET.

SIR,—May I make a small contribution to the possible ambiguities arising in reports of pathological findings? I found the following message on my slate when I came in the other day:—

"They rang up from the hospital to say the telegram has come through, that the swab from the throat is *maggoty* in the boy Smith."—I am, Sir, yours faithfully,

East Grinstead, August 28th. W. HENRY HILLYER, M.D.

*** The Post Office has recently replaced the word *negative* in code telegrams by *not found*.—ED. L.

"WHY AND WHETHER IN FIRST AID."

THIS useful little book (London: John Bale, Sons, and Danielsson, Ltd. 1923. Pp. 100. 1*s*.) was first prepared nearly ten years ago to explain the difficulties in first-aid raised by a large ambulance class, the author successfully putting himself in the position of the student who asks the question. The call for a fifth edition has now enabled Dr. N. Corbet Fletcher to answer a number of queries suggested by correspondents or necessitated by changes in the St. John Ambulance Association text-book. It can hardly fail in its present form to advance the efficiency of first-aid work.

AN INTERCEPTOR FOR DENTAL FOUNTAIN SPITTOONS.

AT the suggestion of Mr. Peyton Baly, M.R.C.S., L.D.S., I have designed a metal box 4 in. by 3 in. by $1\frac{1}{2}$ in., having at one end an inlet elbow-joint with sliding standardised nut for attachment to the cuspidor and upon the under-surface an outlet tube with perforated cover. A perforated removable framework of the same shape as the box, but of smaller dimensions, rests within the apparatus, and is enclosed in one of the surgical napkins used by dental surgeons. As the fluid from the bowl of the cuspidor streams into this receptacle it is filtered both by the small perforations of the metal and by the napkin before it passes through the perforated cover of the outlet. Sputum and other rapidly decomposing material is thus prevented from lodging in the rubber waste-pipe which, as now employed, acts as a trap for this material—a fact well known to those who have attempted to cleanse it by pushing a cork of the same diameter as the bore through it. The box can be easily cleansed by raising the lid and removing the internal fittings. At the end of the day the outlet tube may be closed by the supplied stopper and the box filled with a disinfecting fluid, or the entire instrument may be removed and sterilised by boiling. The need for some such device has long been felt by dental surgeons. The attachment is supplied by dental depôts.

Some Researches
INTO THE PHYSIOLOGICAL PRINCIPLES UNDERLYING THE TREATMENT OF INJURIES AND DISEASES OF THE ARTICULATIONS.*

A Lecture delivered before the Physiological Society of the Middlesex Hospital

By A. G. TIMBRELL FISHER, *M.C.*,
F.R.C.S. ENG.,

LATE HUNTERIAN PROFESSOR, ROYAL COLLEGE OF SURGEONS (ENG.), 1921 AND 1922: SURGEON (WITH CHARGE OF OUT-PATIENTS) AND JOINT LECTURER IN OPERATIVE SURGERY, SEAMEN'S (DREADNOUGHT) HOSPITAL, ETC.

AT the present time the need for research into the physiology of the articulations is urgent; it is my desire to awaken interest and enthusiasm in these difficult and important problems, and my hope that others may be induced to attack them.

Why are these problems important? Because very many stiff and deformed joints might have been prevented by a knowledge of physiological principles; moreover, the restoration of movement to the crippled joints is often possible. The science of manipulative surgery is as yet in its infancy. It is folly to shut our eyes to the fact that in many cases the unqualified bone-setter achieves brilliant results. Hard-headed business men who are directors of football teams often send a professional footballer to an unqualified bone-setter as a last resort. The latter performs certain manipulations and the player is frequently able straightway to resume his professional football, although failures may occur.

Let us be honest, and, instead of decrying the good work done by the bone-setter, conduct research into the underlying physiological and pathological principles. We may rest assured that the mists of ignorance will be dispelled when we adopt the method that John Hunter advised to his friend Jenner, who was thinking of investigating vaccination: "Do not think, but try; be patient, be accurate." It has been truly said that the progress of any particular branch of medicine or surgery from empiricism towards the status of a science depends upon an observance of three great principles or foundation stones—accurate anatomical, physiological, and pathological knowledge.

One of the best examples of the truth of this statement is afforded by the advances of late years in the diagnosis and treatment of tumours and other affections of the central nervous system—advances largely due to anatomical research and to physiological experiment, and to observing the precepts and teaching of that great surgeon and physiologist, John Hunter. In the march of progress certain branches have lagged somewhat behind, none more than the branch which deals with the articulations. The Hunterian tradition has been unaccountably neglected, and it is strange that although injuries and diseases of the joints are amongst the commonest of all human ailments, yet there is not only apathy, but also much ignorance of the underlying anatomical, physiological, and pathological factors.

Is there any type of case which the practitioner finds more puzzling and difficult than an obscure affection of a joint? The diagnosis presents often a most difficult problem, as may also the question of treatment. Apart from minor problems, one of the principal questions that the practitioner must ask himself is, "Shall I, in the treatment of this joint case, immobilise, or shall I permit and encourage movement?" If one may attempt a generalised statement, we may perhaps admit that the practitioner errs too often on the side of immobilisation, and hence the far too many deformed and stiff joints that we encounter daily. The bone-setter who employs movements almost as a routine perhaps errs by neglecting rest when this is indicated. However, the bone-setter is fully alive to a great principle which was summed up by a famous French surgeon in the phrase "movement is life"—a phrase which I should like to see framed in letters of gold in the consulting room of every medical man.

A stiff joint is an affliction, one which the public rightly holds in great dread. The speed and skill of the athlete, the grace of the dancer, the power of the musician to charm our ears, indeed, our daily avocations and amusements, all depend very largely upon the smooth and free gliding of cartilage-clad articular surfaces. Can we wonder that when the public are asked to choose between indiscriminate movement by a bone-setter and immobility, which is, alas, often equally indiscriminate, by a qualified practitioner, it not infrequently consults the former? In my own practice I have constantly been faced with the difficuty of deciding which mode of treatment to adopt. It became clear to me that there was an almost complete absence of guiding physiological principles. Is it surprising, therefore, that in the absence of these guiding principles we find that unqualified individuals exist who reap a harvest in the stiff and deformed joints, often due to unfortunate treatment by our professional brethren? The physiology of the joints presents many interesting and important problems, but time will permit me to deal this evening very briefly with two aspects only—viz., the physiology of articular cartilage and of synovial membranes, together with some general principles of treatment.

ARTICULAR CARTILAGE.

In articular cartilage we have a tissue well suited for studying the behaviour of cells under different conditions, since, save in the perichondrium near the edge, it contains no blood-vessels or nerves to complicate the cellular reactions. It, oddly enough, has been rather neglected by the researchers into the cause of tumours, but I believe that it may furnish much light into this difficult problem, particularly as the irregular proliferations which it undergoes in osteo-arthritis are, I believe, intermediate between inflammation and new growth. When investigating such a complicated and difficult problem as tumour formation, it behoves us to begin at the bottom of the ladder, and to study first the simpler forms of cell proliferation such as we see in repair and inflammation. Next we must study with great care the irregular proliferations that occur in certain diseases of known toxic or microbic origin. We shall then see that all these forms of cell proliferation merge gradually into one another, and it may gradually dawn upon us that it is unjustifiable to draw sharp lines of demarcation between them.

Articular cartilage is a substance well adapted for the functions that it performs. It has in health a smooth surface, lubricated by the synovial fluid, thus reducing friction to a minimum. It is of great strength and is elastic, yielding to blows and concussions which might otherwise damage the subjacent bone. Indeed, we may regard bone as a tissue less endowed with vitality than articular cartilage. For when the latter is destroyed by chronic disease, and pressure is still permitted, the bone becomes absorbed. In a Hunterian lecture on loose bodies in joints,[1] I demonstrated that in detached portions of the articular surface which contain both cartilage and bone, and which have been for some time quite free in the joint cavity, the cartilage cells usually retain their vitality, whereas the majority of the bone cells die. This observation has recently been confirmed by Ito, working in the laboratories of University College Hospital. Kuttner's cases of joint transplantation are of particular interest, as in two of them the joints were examined some time afterwards, the patients having died from an intercurrent affection. Microscopic examination showed survival of the articular cartilage, whereas the bone cells were dead.

---

* The expenses of this research were defrayed by a grant from the Medical Research Council.

[1] British Journal of Surgery, 1920-21, viii., 493.

Axhausen's animal experiments showed practically the same state of affairs; the articular cartilage of the transplanted joint-end lived, whereas most of the cells of the compact bone were necrosed. No true tumours of articular cartilage have been described, and when a malignant growth of the adjacent bone reaches the articular cartilage it is a remarkable fact that the latter forms an almost impenetrable barrier, at any rate for a long period. Can we resist the conclusion that this absence of blood-vessels plays an important part in its immunity from tumour formation? This absence of tumour formation where vessels are non-existent leads us to inquire whether the irregular proliferation of cells that we call tumours may not be due to irritant or toxic substances brought to the selfsame cells through the intermediation of the circulation. I have found experimentally that it is possible to produce small tumours of the lateral part of the articular cartilage by radium.

Experiment 20.—A small glass tube containing 0·0382 mg. radium was introduced into the left knee of a rabbit and fixed by suture against the inner border of the internal femoral condyle near its junction with the trochlear surface. A similar tube but containing 0·15 mg. radium was introduced into the right knee and fixed in a similar position. Nineteen weeks later the animal was killed and the following appearances were noted:—

Left knee: Well-marked proliferation of the articular cartilage at the inner margin of the femoral condyle and trochlear surface. The radium tube had become loose and lay in the supra-patellar pouch.

Right knee: Slight and irregular nodular chondro-osteophyte in same position as in left knee.

It is important to note that the greater amount of proliferation occurred in the left knee—which, however, had contained the smaller amount of radium. I am indebted to Prof. W. S. Lazarus-Barlow for the kind loan of the radium tubes.

Structure of Articular Cartilage.

It will perhaps avoid confusion if we discuss the structure of articular cartilage under two headings—viz., the central and the lateral articular areas. I have endeavoured to show that there is a fundamental difference between the structure and nutrition of these two parts and that this difference is of importance, since it sheds light upon many hitherto obscure pathological phenomena.

Central Articular Area.—It was held by Ogston that the surface cells are degenerate and are in process of being shed into the joint, and that articular cartilage is continually renewing itself by growth of the intermediate zone. Henle has described a delicate layer of cells upon the free surface. If, however, the surface of the *central part* of the articular cartilage be carefully focussed, it will be seen that there is no layer of cells at the actual free surface, but that this is formed of clear matrix with a sharp curvilinear margin. Secondly, the more superficial cells of the articular cartilage, which are flattened conformably with the surface, show no sign of degeneracy and have every appearance of being normal healthy cells. There seems little doubt, not only from analogy with the lateral part of the articular cartilage, but from developmental reasons, that these more superficial cells are the source of origin of the deeper cells and that they behave like the perichondrial cells of costal cartilage. Towards the termination of the second month, the joint cavities have appeared—a split occurring in the mesenchyme. At the fourth month of intra-uterine life the surface of the joint cartilage is still covered by this layer of connective tissue. This is the stage found throughout life in certain birds. With the increasing movements of the child before birth the perichondrial layer gradually recedes from the more central parts of the articular surface, but at birth it still strays for a short distance over its edge. Microscopically, however, the connective-tissue layer can be traced beyond the naked eye delimitation. Shortly after the child begins to walk the extension of the synovial membrane over the lateral margin of the articular cartilage makes a further slight regression, but soon assumes its permanent relationship. No perichondrium is present over the more central part, yet there can be no doubt from a study of their structure, staining reactions, and of their development and comparative anatomy, that these cells have the same function as the perichondrial cells of the lateral part of the articular cartilage, and are the parent cells of the more fully-developed cartilage cells in the deeper parts. In the intermediate zone of the articular cartilage the cartilage cells are arranged in groups and are no longer flattened. In the deeper zone the cells are arranged in columns perpendicular to the narrow subarticular layer of bone upon which they lie.

Lateral Articular Area.—This closely resembles those forms of hyaline cartilage, such, for example, as costal cartilage, which are furnished with a perichondrium, for the synovial membrane gives to this part of the articular cartilage a delicate investment in which well-marked capillaries may be traced. At the edge also the articular cartilage is fibrillated and partakes of the nature of fibro-cartilage. This difference in structure of the central and lateral parts is rendered clear, as we have seen, by a study of the development of a joint and by comparative anatomy.

Nutrition of the Articular Cartilage.

In a paper which has become classical, entitled "Of the Structure and Diseases of Articular Cartilage," William Hunter first described the circulus articuli vasculosis lying near the articular edge and giving delicate offshoots to the lateral part of the articular cartilage. Toynbee did not attach much importance to the circulus as a source of nutrition, but considered that articular cartilage derived its pabulum from plasma exuded from the capillary loops lying in the cancellous spaces beneath the subarticular layer of bone. The synovial fluid has not hitherto been seriously considered as a source of nutrition, but Strangeways, arguing from the increase in size that loose bodies derived from the articular surface undergo while free in a joint, has advanced the view that the synovial fluid is a normal source of nourishment of the articular cartilage. Thus we are faced with three different theories. My own observations lead me to believe that there is an element of truth in each. By delicate injection methods, the subarticular bony layer is seen to be freely permeable by the injection matter, and it is probable that nutrient plasma is also able to permeate this zone and nourish the deeper layer of the cartilage. Laterally the subarticular layer is actually penetrated at certain spots by blood-vessels which can be traced for short distances in the cartilage.

With regard to the rôle played by the synovial fluid, we are faced with the fact that there is no evidence that the analyses hitherto recorded are of fluid obtained from normal joints. Indeed, evidence derived from the data given, with the few analyses hitherto recorded, points to the fact that the fluid was derived from pathological conditions such as synovitis with effusion. Such inflammatory effusions have a somewhat high protein content. The analysis of normal synovial fluid collected by myself in the post-mortem room gave results of considerable interest and may be summarised in the form of a table.

Average Personal Cases.

—	Synovial fluid percentages.		Lymph plasma percentages. Human.
	Human.	Oxen.	
Total solids ..	4·41	2·023	4·2–6·5
Protein content ..	1·6	0·92	3·5–4·3
Mucin	1·95	0·1303	—

In spite of the somewhat low protein content shown in the table, I believe that the synovial fluid nourishes the superficial cells of the central articular area; and this same low protein content accounts for the feeble powers of resistance of this part of the articular cartilage and the readiness with which it undergoes degenerative changes, and the extreme slowness or even absence of repair in the central part of the articular cartilage. I found by systematic examination of joints from the post-mortem room that 80 per cent. of individuals between 50 and 60 years of age and 90 per cent. between 60 and 70 show more or less of fibrillation of the central part of the articular area.

I believe that the deeper layer of the articular cartilage is nourished from the capillaries in the subarticular cancellous spaces, and that the lateral part of the articular cartilage receives in addition a supply of lymph from the capillaries of the circulus articuli vasculosus.

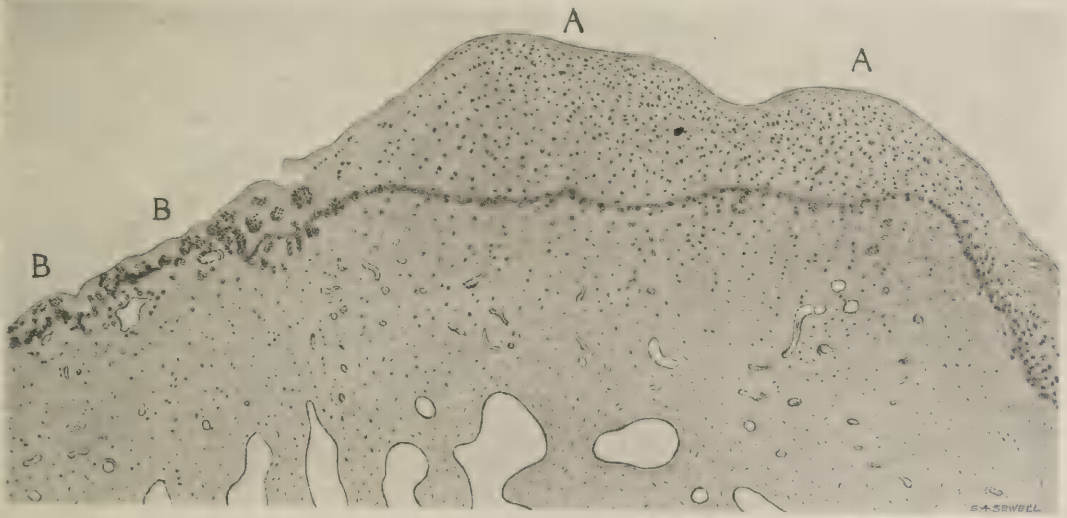
Repair in Articular Cartilage.

The phenomena of repair are a striking confirmation of the views enunciated above. I have confirmed Redfern's experimental findings that incisions in the central part of articular cartilage heal, if at all, with great sluggishness, and that there is an absence of cartilaginous repair. Incisions in the lateral portion, however, exhibit much more active repair, and there is a new formation of articular cartilage in which both cartilage itself and perichondrium participate.

Experiment 18.—A transverse incision was made in the trochlear surface of the femur of a rabbit and through the whole thickness of the articular cartilage. Seven and a half months later the animal was killed, and microscopic examination (Fig. 1) showed little if any sign of repair. It will be seen that the articular cartilage to the right of the incision has undergone necrosis and is being invaded by multinucleated chondroclasts.

This difference is even more markedly demonstrated when the articular cartilage is completely removed with exposure of the subjacent cancellous spaces. Laterally a pannus of granulation tissue derived from the synovial membrane and supplied by the circulus spreads over the denuded zone and assists in forming new cartilage. In the central areas the formation of new cartilage is less marked and occurs through the agency of the connective-tissue cells of the exposed cancellous spaces. In the experiment mentioned above the inner portion of the femoral condyle was chiselled away, leaving a flat surface of cancellous bones. The microscopic appearances as seen seven and a half months later are shown in Fig. 2. On the left side of the drawing may be seen a feeble attempt at new cartilage formation from the exposed cancellous spaces. In the centre and on the right there is an exceedingly marked formation of new cartilage which is largely derived from the perichondrium upon the surface. In addition to its nutritional duties we may therefore regard the circulus articuli vasculosus as a very important factor in the destruction and replacement of diseased cartilage and in the repair of deficiencies in its lateral part. It is the vascular supply of the pannus of granulation tissue which spreads like an advancing tide over the surface of the cartilage in many forms of arthritis.

FIG. 2.

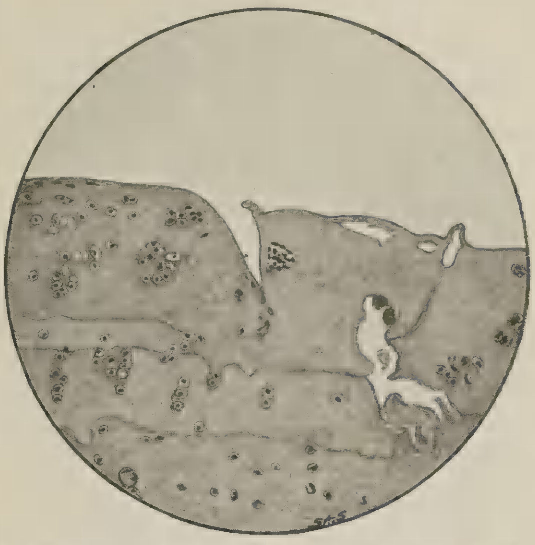


Portion of lower end of femur of rabbit 7½ months after articular cartilage had been chiselled away, with thin layers of subjacent bone. AA, marked reparative formation of new cartilage laterally. BB, feeble formation of new cartilage in the more central zone. Obj. 2/3 in.

Compensatory Proliferation of Lateral Part of Articular Cartilage after Destruction of Central Part.

This fact, which I was able to demonstrate experimentally,[2] forms in my opinion one of the most striking examples of adaptation in the human body, and it seems clear that the "lipping" that occurs in osteoarthritis, particularly the traumatic type, is an attempt by the better nourished lateral portions to compensate for the loss of the central parts *by extending the articular surface.* This view, although it may savour of metaphysics, I believe to be of great importance, for it is clear that, if aided by judicious treatment, these osteophytes may play a useful part, and their indiscriminate removal when causing no obstruction to movement is to be deprecated.

FIG. 1.



Experiment 18 (rabbit). Incision in centre of articular cartilage of trochlear surface of femur after 7½ months, showing absence of repair. Obj. 1/6 in.

I have endeavoured to show that the loss of the central articular cartilage may be due to trauma or to the action of toxic or poisonous substances, and that in the latter case the same toxins may cause degeneration of the poorly nourished central portion of the articular cartilage and proliferation of the better nourished lateral parts. The term toxin is to be used in its broadest sense, and there is evidence that these toxins may be bacterial in origin. There is, however, a danger of emphasising the importance of bacteria in the ætiology of disease. The occurrence of osteo-arthritic changes in certain disorders of the ductless glands, and its frequency at the menopause, certainly suggest that the toxins are due to failure of a ductless gland or glands to supply some links in the chain of metabolic endogenous products, or that possibly by this same failure the resistance of the patient to infection may be thereby lowered. There is evidence also that osteo-arthritis may be due to auto-intoxications such as those due to defects in the excretory apparatus or the accumulation in the body of products of normal or abnormal metabolism.

---

Mode of Access of Nutrient Fluid to Cartilage Cells.

No definite lymphatics with endothelial lining have ever been demonstrated in articular cartilage. How, then, do the cartilage cells obtain their nourishment? The intercellular material of articular cartilage is composed of mucin and collagen in various proportions. If articular cartilage is stained by carbol-thionin, which stains mucin pink, it will be found that the zone of matrix immediately surrounding the cell groups is stained deeply and is evidently the most recently formed and more mucinous part. On examination of a well-stained section the pink zones branch and communicate and form a network surrounded by a series of more faintly stained zones evidently formed of collaginous matrix. In the superficial area the layers are horizontally arranged, and in the deeper zone the arrangement is vertical. If articular cartilage is steeped in brine, these layers become prominent, and if it be fractured at right angles to its surface, the arrangement in perpendicular fibres like the pile of velvet is very striking. There is strong evidence from the nature of the earlier changes in osteo-arthritis that there is a solution of these same mucinous paths and that the fibrillation is due to the persistence of the columns of more collaginous matrix.

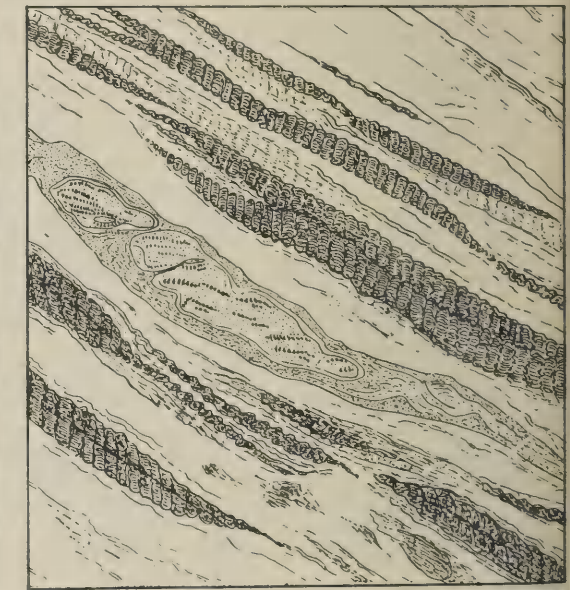
PHYSIOLOGY OF THE SYNOVIAL MEMBRANES.

It is quite impossible in the time at my disposal to give more than a brief summary of my researches into the structure and functions of the synovial membranes. I find that this membrane differs markedly in its structure at different situations in the same articulation. At the parts most remote from the articular edges it consists of a single layer of endothelial-like cells which in places surround openings or stomata. Beneath the endothelial layers is a layer of loose connective tissue rich in capillaries, nerves, and lymphatics. Here and there the endothelial layer is absent, and at these spots the loose connective-tissue layer abuts directly upon the joint cavity. This absence of a complete endothelium may account for the grave toxæmias of acute suppurative arthritis.

Nearer the articular margins the endothelial layer is very deficient, as it is also at the margins of the villi—the latter being almost exclusively confined to the portions of the membrane nearest to the articular margin. The most striking feature of the membrane in the latter situation and in the villi is the presence of great numbers of deeply staining, oval or round, connective-tissue cells, which may form superimposed layers. The nuclei of these cells are spherical or oval and of the reticulated connective-tissue type. The function of these cells appears to be the secretion of the synovia, and the absence of a complete endothelial layer readily allows the synovia, assisted by the joint movements, to escape into the joint. On staining synovial membranes with carbol-thionin (Fig. 3) I discovered globules of mucin in the cell bodies, and every stage of transition between well-marked granules and definite droplets of mucin may be seen. In some cases the cell can be seen to be distended with mucin and the nucleus compressed.

I believe that the mucin gains the joint cavity in three distinct ways: (*a*) The cells at the surface discharge their mucin into the joint cavity. (*b*) Certain of the deeper cells discharge their mucin into the loose connective-tissue spaces of the villi, whence it is squeezed out by the joint movements. (*c*) In chronic synovitis, and possibly in normal joints, portions of the surface layer of the membrane are detached and the mucinous transformation takes place in the joint cavity; the cell bodies forming the cellular débris normally present in the synovial fluid. In some, cartilaginous transformation can be seen to be taking place.

FIG. 4.



End-bulb of nerve between tendon fibres attached to patella. (Drawn by Dr. R. J. Gladstone.) Obj. 1/6 in.

The membrane surrounding certain fatty processes projecting into joints, such as the infra-patellar pad of fat, is so richly furnished with these secreting cells that the name "synovial glands," originally given to them by Clopton Havers, seems amply justified. There can be little doubt also that, as Havers suggested, the pressure caused by the normal joint movements causes an increased outpouring of mucin. This fact was proved by Freidrichs, who examined the synovial fluid of oxen after rest and after exercise. Whether there is, in addition, a nervous mechanism, it is impossible at present to state. That this is the case is, however, suggested by the interesting condition of intermittent hydrathrosis. In addition to the power of secreting mucin, which is a pure lubricant, we must not forget that the synovial membrane allows the transudation from the rich plexus of capillaries with which it is supplied of the albuminous fluid which, in my opinion, nourishes the central superficial area of the articular cartilage. It is not generally realised that the synovial membrane is richly supplied with nerves. By special staining methods I have observed delicate nerve fibrils forming a plexus in the sub-endothelial layer, also a further plexus immediately beneath the secretory layer of cells. Connecting these two plexuses are delicate fibrils, and in certain of the villi I have observed end bulbs (Fig. 4). Nicoladoni described Pacinian capsules in the articular capsules in the rabbit. I have observed similar bodies in man in the anterior wall of the supra-patellar pouch lying immediately beneath the synovial membrane. It is highly probable that many of the nervous phenomena that occur in certain joint diseases, particularly in rheumatoid arthritis, are reflexly produced and are caused by inflammatory involvement of the synovial nerves and nerve-endings. These nervous phenomena are often so prominent that by many the disease is considered primarily "neurotrophic" in nature, but it seems more probable that the vasomotor and articular symptoms are due to the action of some common cause.

Physiology of Absorption by the Synovial Membrane.

That master physiologist, Claude Bernard, wrote in 1859 with regard to the synovial fluid, "les données physiologiques sur ce liquide sont à peu près nulles: le siége anatomique de sa sécrétion est lui-même très peu connu." These words are well-nigh as true to-day as when they were written more than 60 years ago, and otherwise exhaustive treatises on physiology dismiss the subject in a few lines as one of no importance or interest. The behaviour of the synovial membrane towards various fluids differs considerably with the chemical and physical composition of the latter. In this part of my research I have received helpful suggestions from Dr. Bolton, whose work on absorption from the peritoneal cavity is well known. I propose here merely to recite a few typical experiments.

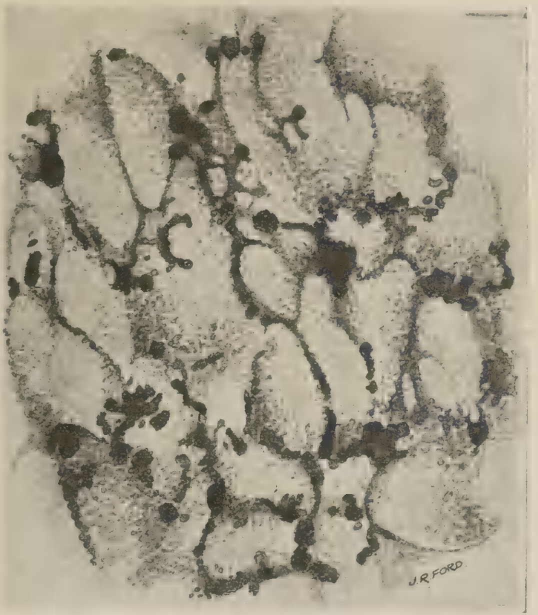
Absorption of Isotonic Solutions.

Experiment 6 (old series).—In this experiment I was kindly assisted by Prof. S. G. Shattock. The needle of a 5 c.cm.; syringe was inserted obliquely into the inner side of the supra-patellar pouch of an anæsthetised rabbit; 1·5 c.cm. of a sterile solution of isotonic potassium iodide was then slowly injected until the joint became tense. Absorption appeared sluggish at first, but, after alternate flexion and extension of the joint, which was repeated several times, there was appreciable slacking of the joint tension. Sufficient fluid was then injected again to distend the joint cavity. The experiment was continued for five hours, and at intervals of 15 minutes 1 c.cm. of the solution was introduced. The total amount of isotonic potassium iodide absorbed during this period was about 20 c.cm. Urine collected from the bladder at the termination of the experiment gave the typical starch reaction, showing that the potassium iodide solution had been absorbed by the synovial membrane and finally excreted by the kidney. The experiment also demonstrates the important part played by movement in assisting the absorption of the fluid. It is obvious that this process of absorption might have occurred by means of either the capillaries or lymphatics, or possibly both may have played a part. A further series of experiments was performed in an endeavour to ascertain the respective part played by these different elements. These experiments are as yet incomplete, but it is possible to state a few preliminary observations.

Absorption of Diffusible Dyes.

Experiment 9 (old series).—The above experiment was repeated, using a solution of Berlin blue; 2 c.cm. were injected into the joint, gentle movements were instituted, and after a short interval a further 1 c.cm. was injected. At the completion of the experiment the animal was killed and the joint opened and examined. A small quantity of the Berlin blue solution remained in the joint. There was a generalised diffuse staining of the membrane present, more marked in the supra-patellar pouch. On further examination it was seen that the dye lay in the sub-endothelial layer of the membrane, but no injected lymphatics could be detected either proximal or distal to the joint. Microscopic examination of a portion of the membrane from the supra-patellar pouch showed an absence of lymphatic injection save at one small area. This experiment would appear to point to the fact that diffusible dyes are somewhat rapidly absorbed by the capillaries into the venous circulation and only to a slight extent by the lymphatics.

FIG. 5.



Demonstration of lymphatics of synovial membrane by injection of colloidal silver into knee-joint of a living rabbit. The lymphatic glands along the iliac vessels and abdominal aorta also strikingly demonstrated. Obj. 1/6 in.

Absorption of Colloidal Dyes of Greater Molecular Composition.

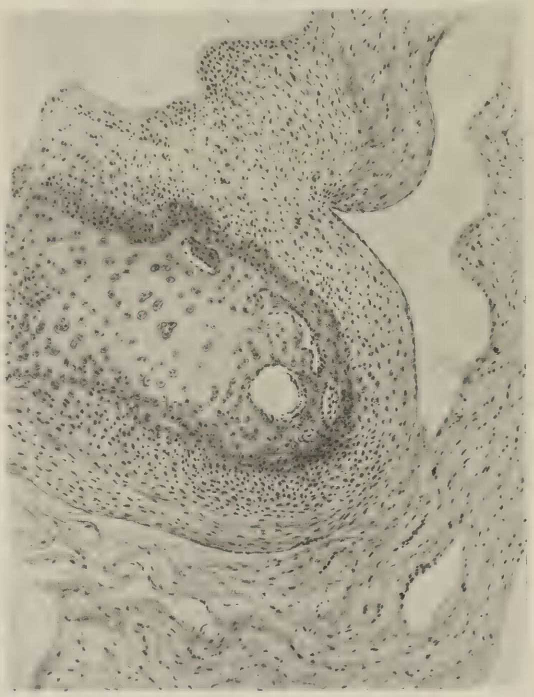
(*a*) *Berlin Blue and Mucilage of Tragacanth. Experiment 1* (new series).—A saturated aqueous solution of Berlin blue mixed with an equal quantity of mucilage of tragacanth was prepared to approximate as closely as possible to the composition of normal synovial fluid; 1·5 c.cm. were injected into the knee-joint of a rabbit; the animal was allowed to move freely about, and was killed in five hours. It was found that absorption by the lymphatics had certainly taken place, for microscopic examination of the membrane revealed these clearly. No obvious staining of the lymphatic glands was detected. The striking thing, however, was that the whole of the circulation of the animal was stained a vivid blue, showing that absorption by the capillaries had readily occurred.

(*b*) *Colloidal Silver. Experiment 4* (new series).—Adopting a suggestion of Dr. Bolton, a solution of 2 per cent. colloidal silver in normal saline was injected into both knee-joints of a rabbit. The animal was allowed to move about freely until killed five hours later. The synovial lymphatics were thus demonstrated in a very striking manner (Fig. 5) the colour varying from dark brown to black. Furthermore, the popliteal gland, the lymphatics along the course of the femoral vessels, the iliac glands, lymphatic vessels along the course of the abdominal aorta, and even glands near the entrance of the thoracic duct, were demonstrated. There was a certain amount of absorption into the general circulation, but it is not possible at present to state whether this was due to absorption of colloidal silver by the synovial capillaries directly into the blood stream or whether the silver had gained access to the circulation through the thoracic duct. It is probable that both occur, but that in the case of such colloidal substances the principal route of absorption is through the lymphatics.

I was able to prove experimentally that movement, as in the case of the isotonic solutions and diffusible dyes, plays a very important part in the absorption of colloidal silver.

In another series of experiments a similar quantity of colloidal silver was injected into the knee-joints of two rabbits. In one rabbit the joint was immobilised, whilst the other was allowed to move freely about. At the end of a fixed period of time both animals were killed. It was found that in the immobilised joint the lymphatics in the synovial membrane could usually be demonstrated, but no proximal lymphatics or glands were stained. In the case of the animal in which movement had been permitted, the proximal lymphatic vessels and glands were demonstrated by the colloidal silver in a very beautiful manner. As an instance the following experiment may be quoted.

FIG. 6.



Transverse section through experimental loose body after 7½ months. The difference between the original cartilage and that formed upon it by the synovial membrane which surrounds it is very striking. Obj. 2/3 in.

Experiment 5 (new series).—Rabbit B: 1·25 c.cm. of colloidal silver (2 per cent. in normal saline) injected obliquely into supra-patellar pouch of right knee at 10.30 A.M. No obvious extravasation occurred and puncture was sealed with collodion gauze. The animal was permitted to move about freely on recovering from the anæsthetic and was killed at 12.8 P.M.

Rabbit A: Similar injection made into the right knee at 10.50 A.M., but animal was kept under anæsthetic and no movement occurred. It was killed at 12.28 P.M.

Post-mortem examination: Diffuse staining of synovial membrane present in the injected knee of both rabbits. In Rabbit A no lymphatic glands or lymphatics proximal to the joint were stained, whereas in Rabbit B, in which movement had been permitted, the popliteal gland was stained a dark brown, the iliac glands on the right side were stained a light brown, and there were a few faintly stained lymphatics along the abdominal aorta.

The practical lessons that these preliminary experiments appear to teach will be touched upon later. I am indebted to Prof. Shattock for verifying the presence of lymphatics in microscopic preparations of the synovial membrane.

Behaviour of the Synovial Membranes towards Foreign Bodies.

In some previous experimental work upon the loose bodies occurring in joints I found that a detached portion of the articular surface almost invariably became attached to the synovial membrane, and that the latter surrounds it with a connective-tissue sheath. This sheath has, however, a very remarkable quality. It has the power of laying down layer upon layer of cartilage (Fig. 6) and even bone upon the surface of the body, until, occasionally, veritable tumours are formed. In many cases these bodies may later become detached from the membrane and continue their growth while quite free in the joint and deriving their nourishment from the synovial fluid. The nutritive value of the latter is, however, often increased by inflammatory exudate.

An enormous literature has developed concerning loose bodies in joints. Moreover, they have been a pathological puzzle for many generations. I may humbly claim to have been the first to attack the problem from the experimental point of view, and I was gratified when a Japanese investigator, Dr. Ito, working in the laboratories of University College Hospital Medical School, confirmed my experimental findings two years later.

SOME APPLICATIONS OF THE ABOVE PHYSIOLOGICAL PRINCIPLES TO TREATMENT.

1. *The Rôle of Rest.*

It may be considered an axiom that Hilton's dictum, "Rest inflamed structures," should be applied to most cases of acute inflammation affecting a joint. There are, however, certain reservations to be dealt with below. We must, in addition, constantly bear in mind that the function of a joint is movement, and that Nature's method of cure is by ankylosis and often ugly deformity. The policy of leaving the matter entirely to Nature is heartily to be deprecated. Deformity must be prevented by extension or other methods which prevent that spasm in which the powerful groups overcome the weaker and cause deformity. The limb should be placed, as Sir Robert Jones has so often pointed out, in that position which, should ankylosis occur, is of the best functional advantage to the patient, whose occupation and amusements should, moreover, be carefully considered.

We are too often apt to rest content with such ankylosis, but by instituting earlier movements very cautiously and gently when the acute symptoms are subsiding we may be able to retain a useful degree of movement. This does not, however, apply to tuberculous arthritis. The risk of lighting up the disease and of general dissemination is so great that, except in certain very chronic forms, absolute immobility of the joint should be maintained for several months after all acute symptoms have subsided. Even in these cases, however, by suitable treatment our ideal of a movable joint may be obtained where advanced destruction of articular surfaces has not occurred. In the non-infective types, such as traumatic synovitis, sprains, &c., a combination of rest and skilfully applied movement is of great advantage. For instance, in a case of traumatic synovitis of the knee rest in bed or on a couch to avoid weight-bearing and undue irritation is advisable at first; but massage and gentle movements not only allay pain but cause the more rapid absorption of intra-articular effusion and prevent subsequent stiffness. This is combined with elastic pressure and firm bandaging over a thick layer of wool completely surrounding the joint. In a case of severe sprain of the wrist rest from active use of the joint and of the hand is indicated at first, but massage and gentle passive movements may be instituted at once.

2. *The Rôle of Movement.*

(*a*) *Acute Inflammations of Joints.*—The rôle of movement in acute inflammations of joints is naturally a limited one. In cases where the articular cartilages have been destroyed the pain and spasm produced by even the slightest movement are so intense that it is ruled out of practical politics. Furthermore, there is serious risk of general dissemination. However, in cases where the suppuration is largely limited to the synovial membrane excellent results may accrue, if free drainage is provided. The pioneer work of Willems is of interest in this connexion. I recall a case of suppurative arthritis of the knee-joint, treated thus during the recent war, which I have been able to follow up. Two long lateral incisions were made for drainage, and the posterior compartment of the joint was also opened up by lateral incisions in the popliteal space, through which the joint cavity was periodically irrigated with eusol. In spite of every care the patient's condition deteriorated, and it became obvious that unless the recognised alternative of amputation was performed his life was in jeopardy. I determined to try the effect of movements of the joint. Although these were of necessity painful, the condition was explained to the patient and he loyally and intelligently coöperated. At the first movement there was a gush of pus from the drainage sites, and this was noticed at each subsequent movement. The patient recovered with a full and painless mobility. I had an opportunity of examining him a few months ago. The joint appeared perfectly normal, and to demonstrate its excellent function he hopped round my consulting-room on the previously affected limb. If this case had been treated in the recognised manner it is certain that amputation would have been necessary. It seems clear that the rationale underlying this treatment depends not only upon the prevention of ankylosis but upon the improved drainage that occurs. During flexion and extension certain synovial recesses are compressed and others cease to exist, and the pus, taking the line of least resistance, escapes via the openings for drainage. If the latter did not exist there would undoubtedly be risk of diffusion of the septic material along intermuscular planes.

(*b*) *The Rôle of Movement in Chronic Non-tuberculous Arthritis.*—It is difficult to have a better example of the principles we have enunciated than in the treatment of those exceedingly common diseases of the joints, osteo-arthritis and rheumatoid arthritis, or, as I prefer to call them, modifying slightly Nathan's nomenclature, chronic arthritis of the chondro-osseous and synovial types respectively. What is the result of *complete* rest in these chronic inflammatory conditions? The synovial membrane and capsule undergo sclerosis, movement is still further obstructed by osteophytes developing at the articular margins, there is secondary shortening of tendons and other periarticular structures, and the joint slowly but surely becomes more and more fixed, often in a position of gross deformity. There exist thousands of men and women who drag their stiff and deformed joints from one spa to another and whose deplorable condition might have been prevented by remembering the dictum that "movement is life." These deformities are nearly all preventable by attention to three main principles, and it is unfortunate that many text-books still speak of the stage of "sequels" as if the latter were inevitable and unpreventable. These principles are as follows:—

1. The joint or joints should be put through the full range of movement daily *although over-exertion is to be avoided*, every effort being made to preserve the nutrition of the joint structures and to maintain muscular tone.

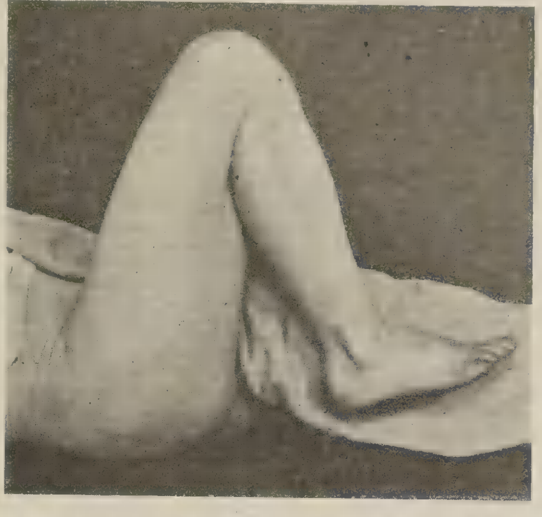
2. In most articular cases, particularly in the lower extremity, the principle of diminution of intra-articular pressure is to be observed.

3. The cause must be simultaneously attacked. There is no greater misapprehension than to imagine that chronic non-tubercular arthritis is of necessity a disease which steadily progresses. I have seen very many cases in which the disease has ceased, and it should be a point of honour with our profession so to act that when this happy result accrues the patient still retains a movable joint. The movements, in addition to preventing scarring of the soft parts, cause the osteophytes to develop in such a way that they do not interfere with movement. In other words, it is possible to train up an osteophyte in the way it should grow. It is not sufficiently realised that in many of the aforementioned sufferers the disease has come to an end and that their symptoms are caused by the deforming stiffness. Medical treatment is of doubtful benefit in this type of patient. The locked joint is crying out for movement. This can be restored by various surgical measures, but particularly by manipulation, a most valuable procedure in suitable cases. The results are sometimes almost dramatic; patients have been restored from lives of painful crippledom to comparatively painless activity. One with very marked changes in the hip-joint is now able to run and even jump (Fig. 7).

Another helpless cripple in whom both hip-joints were affected and who had received every imaginable form of medical treatment and had visited most of the spas in England and Europe is now, after tenotomy of the adductors and manipulation, able to ride a horse and swim.

Manipulation is not advisable in the more acute forms, as it may give rise to a reaction, after which the joint gradually stiffens once more. It is never necessary, and it may be dangerous, to use extreme force. Such a procedure, especially in feeble or debilitated individuals, may be associated with considerable shock, and in these cases it is well to be contented with gradual restoration of full movement by repeated manipulation. Whole-hearted coöperation by the patient in the after-treatment, which may be long, and optimism on the part of the surgeon, are invaluable adjuncts. It is obvious that where movement is obstructed by osteophytes, and in certain other cases, open surgical operation may be indicated. I do not propose, however, to deal with operative treatment now.

FIG. 7.



Showing the degree of active flexion of the right hip after manipulation in a patient with marked osseous changes in the joint. Although previously crippled and subject to severe pain, the patient is now leading an active and comparatively painless existence.

In rheumatoid arthritis, where there is a still greater tendency to limitation of movement, the same lines of treatment are indicated. If anything the indications are even greater, since there is a special tendency in this disease for adhesion between articulating surfaces to occur.

(*c*) *The Rôle of Movement in Chronic Synovitis with Effusion.*—It has long been known that pressure is a valuable factor in bringing about the absorption of "water on the knee" and other joint effusions. The experiments with colloidal silver cited above furnish corroboration from the laboratory of the valuable and important rôle played also by movement in the absorption of an intra-articular effusion. We should bear in mind, however, that the amount of movement should be carefully regulated; for excessive movement will almost certainly cause an inflammatory reaction with the outpouring of an increased amount of fluid.

(*d*) *Early Movement in Injuries or Fractures Involving Articular Surfaces.*—When an injury has caused a loss of substance of the articular cartilage, with exposure of the subjacent cancellous bone, in the absence of movement the irruption of connective tissue from the exposed cancellous spaces is apt to form a bond of union with the opposing articular cartilage. If there is a corresponding loss of articular cartilage on the opposed surface, such adhesion is even more likely to occur. Early movement is imperative in such cases, and there is no evidence that movement, however early, militates against repair of the articular surfaces. I have ascertained experimentally that after excisions of portions of the articular surfaces followed by immediate movement repair proceeds normally. I endeavoured to emphasise in a paper read at the first Congrès International de Médecine et de Pharmacie Militaires, held at Brussels, that the principle of early movement applies with special emphasis to cases of gunshot wounds of joints in which primary union without septic complications has occurred. Such results were not impossible by taking pains and by careful surgery, and it was galling when a stiff joint resulted from improper after-treatment over which the operator had no control. The following case illustrates this point:—

Lieutenant A. was admitted to a C.C.S. August 10th, 1918, with a perforating shell wound of the left knee-joint. The missile entered at the outer side of the ligamentum patellæ, traversed the anterior compartment of the joint in an upwards and inwards direction, and emerged through the quadriceps tendon 1 in. above the patella. In its course the missile caused comminution and loss of substance of the outer fourth of the patella. The edges of the entrance and exit wounds were completely excised, including the affected portions of synovial membrane. Many small loose portions of bone were removed from the joint cavity. Troublesome oozing from the fractured patellar surface was stopped by means of Horsley's wax. Some little trouble was experienced in closing the lower opening in the synovial membrane, but eventually, by undercutting, the external semilunar pad was utilised and a satisfactory closure made.

This officer's subsequent progress is indicated in the following extracts from letters:—

August 26th, 1918 (he writes from a London Hospital): "I left the C.C.S. on the 11th and went down to No.— General Hospital. The doctor there was rather surprised when he saw my knee. He said I was very lucky and marked me for 'Blighty.' I left the next day. Last Tuesday a medical board decided I would be fit for home service in three months and G.S. in six months." Oct. 29th, 1918: "The leg is practically stiff at present. I have had no actual treatment for five or six weeks. Whether they are going to massage or not I don't know. At present they seem to be leaving it alone and allowing the leg to gradually regain strength. There is no pain at all. Do you think it will remain stiff?"

In June, 1921, he writes as follows:—

"You will be disappointed to hear that my knee is still stiff. The range of movement is practically nil, but on the other hand it is never painful or swollen. The wound remained aseptic throughout . . . The leg was left in the splint for three months, and although I asked the doctor what they were going to do as regards massage, nothing was done. Finally I persuaded another doctor to send me to the massage department, where they told me I had come too late. The leg was then quite stiff and immovable. I asked to be invalided out, as I was anxious to get back to work."

Such a story, only too common during the war, was obviously due to lack of even the most elementary knowledge of physiological principles. The principle of early movement in the case of fractures into joints associated with complete solution of continuity of the contiguous shaft is equally important, although to attain it sometimes taxes the mechanical skill and ingenuity of the surgeon to the uttermost. The war gave a great impetus to this problem. Willems, in a paper read at the aforementioned congress, emphasised the rarity of the indications for the classical treatment of such cases by immobilisation in pre-war types of splints and urged the adoption of extension applied directly to the lower fragment of the fracture. This, among other advantages, made possible the mobilisation of the joint from the start. In the non-compound fractures into joints met with in civil life the same early immobilisation may be allowed by operative fixation of the fragments in suitable cases.

(*e*) *Early Movement after Excision with the object of obtaining Movable Joint or Arthroplasty.*—There has been much discussion concerning the nature of the flap to be interposed in the latter procedure. My own clinical and experimental experience causes me to question whether the principle of early movement does not far transcend in importance any considerations concerning the nature of the flap. Are the reasons put forward in favour of arthroplasty based upon really sound scientific foundations?

It is argued that the interposed medium secures easy gliding of the new joint surfaces upon one another, prevents synostosis, and causes the formation of a new synovial cavity. It may be argued, however, that provided early movement is instituted, Nature very rapidly repairs the exposed cancellous spaces—a connective-tissue covering being formed partly by ingrowth from the periosteum at the periphery, and partly by an eruption of connective tissue from the cancellous spaces. I found, moreover, that gradually this connective tissue layer became converted into cartilage, which may eventually mimic somewhat closely normal articular cartilage.

In reply to the second argument we would ask whether early and sustained movement may possibly be more effective in preventing union than interposition of various substances. The argument that the fascial flap is necessary for formation of a new synovial membrane appears somewhat unsatisfactory when we consider that the connective tissues are perfectly capable of constituting quite excellent synovial membranes without any outside assistance as we see in false joints

I wish not to condemn arthroplasty, but merely to point out that we stand in need of further research into this problem.

In conclusion, let me state my conviction that much work remains to be done before the surgery of the articulations rests upon firm foundations.

Some Common Conditions

REQUIRING

ANTE-NATAL CARE.

A Post-Graduate Lecture delivered before the Fellowship of Medicine

By ROBERT A. HENDRY, M.D., B.S.Lond.,

LECTURER IN OBSTETRICS AND GYNÆCOLOGY, LIVERPOOL UNIVERSITY; HON. ASSISTANT GYNÆCOLOGICAL AND OBSTETRICAL SURGEON, ROYAL INFIRMARY, LIVERPOOL; HON. ASSISTANT SURGEON, LIVERPOOL MATERNITY HOSPITAL.

Ante-natal care is a subject on which so much has been written that there is little ground still unexplored. To-day I propose to consider some of the commoner conditions met with during six years of fairly intensive ante-natal work rather than attempt to deal exhaustively with any one particular section, and to state my personal views for what they are worth, rather than to give a summary of other people's views. Naturally there will be many conditions which I shall not even mention.

The majority of patients attending the clinics were suffering from the minor ailments of pregnancy, gastro-intestinal disturbances being probably the commonest. Of the many remedies for excessive vomiting—not the full-blown hyperemesis gravidarum where the patient is seriously ill and obviously in need of institutional treatment, but for the much commoner variety which merely makes life a burden—I have found the ordinary mist. aperiens alba in about one-quarter to one-eighth of the usual dose, given in several ounces of water, to be so reliable that patients rarely neglected coming back steadily for supplies; and as this meant waiting for sometimes two hours on a draughty landing, my opinion of mist. alba remains high. In other cases, particularly when I thought there was a toxæmic element, Burney Yeo's chlorine mixture has proved of value; the fact that patients continue to take it steadily is sufficient evidence of their opinion.

CONSTIPATION IN PREGNANCY.

Constipation is particularly common in pregnancy. In the poorer classes seen at ante-natal clinics there was little use in giving elaborate directions as to diet, &c.; only too often when a patient attended irregularly the reason was found to be the lack of the few coppers to pay for the medicine, and considerable difficulty was experienced in persuading them to accept anything gratis. Patients' statements of the condition of the bowels require to be received in a critical spirit—the daily evacuation of a few small, hard pellets is, to some, satisfactory evidence that all is well. One lady was not to be shaken from her statement that the bowels acted "regularly"; as her colon was throughout several inches in diameter I was sceptical and inquired—humorously, as I thought—"About once a fortnight?" to which she replied, "Yes, doctor, about that." Sometimes one can only get the reply that the bowel acts "regularly," and further questioning reveals this "regularity" to be in relation to a dose of medicine. Castor oil in particular seems to have some special virtue in the popular regard because one was frequently asked, "When am I to take the oil?" Whether the medicine was taken daily, weekly, or at some irregular interval was usually quite unknown. In such cases, in fact I may say that in the majority of cases, I just took it for granted that the patient was constipated.

A wide choice of drugs is available for the treatment of constipation. As I have indicated, the majority of general and dietetic measures were usually out of the question, and I eventually came to rely chiefly on the mist. alba supplemented by the B.P. pil. aloes et ferri. Aloes is, unfortunately, reputed to have some deleterious effect in pregnancy: after watching the effects of these pills continued over prolonged periods in some thousands of cases my only objection is the inefficiency in a fair number of cases, even when given thrice daily. In such cases pil. colocynth. and hyoscyamus usually proved effective, but even then one had sometimes to give two or even three daily. Where flatulence was distressing a rhubarb and soda mixture was usually substituted for the mist. alb., and I found it acted best when given in hot water after food. Probably about nine-tenths of the cases required, or at any rate received, treatment for constipation, intestinal stasis, and fermentation.

There is great divergence of opinion as to the part played by constipation in the production of disease; personally I am quite satisfied that it is an important factor and that it is responsible for many of the discomforts, and possibly for the origin at least of some of the toxæmias of pregnancy.

ECLAMPSIA, DYSTOCIA, &C.

It is interesting to note that out of about 6000 pregnant women who attended the ante-natal clinics at all regularly not one developed eclampsia. I do not, of course, include patients who attended for the first time with obvious pre-eclamptic symptoms. Such cases were sent at once into hospital or the rest home for adequate treatment. The significance of this is even more striking when I remind you that eclampsia is reputed to occur about once in every 500 pregnancies.

Frequency of micturition is another common complaint, and one for which sometimes no apparent cause can be found. This complaint is often relieved by mist. alba. Why this should be so is not quite clear; it is certainly not due to any resulting looseness of the bowel draining off the fluid, as the small non-purgative doses usually act best. Another unexplained curative effect is that of sodium bicarbonate on the cramps of which complaint is so often made: the cramps that occur in the hip and thigh and are sometimes said to be due to the pressure of the head or the uterus on the lumbo-sacral plexus. I am rather sceptical about this explanation, as the cramps occur chiefly at night, especially when the patient lies on the affected side, which, by the way, remains usually constant. Were they due to pressure, one would expect this to be increased in the day-time and relieved by lying down; when lying on the side the uterus tends to fall away from the pelvis, as is so well seen in the Sims position; and further, one would not expect the bicarbonate to have any effect.

Another direction in which ante-natal supervision is of great value is in the prevention of dystocia. The ease with which the usual external measurements of the pelvis can be made is, I fear, closely paralleled by the rareness of cases in which they are made by the majority of general practitioners. The easily recognised gross pelvic deformity usually carries with it its direct appeal for special treatment in nursing home or hospital. The difficulty—from the point of view of preventive medicine—arises in the less easily recognised minor degrees of contraction and the cases of contracted outlet, and is best met by a full examination in the neighbourhood of the thirty-sixth week of pregnancy. The height of the fundus verifies the period of gestation; previous measurements of the pelvis are confirmed, the position, &c., of the baby determined, the fœtal heart sounds heard, and the head used as a pelvimeter—the best pelvimeter, as Pinard states. My experience is that at the thirty-second week or even earlier the head usually lies in the pelvis—that is, with its greatest diameter below the brim. One can easily demonstrate that with a patient in the recumbent posture the sacral promontory is rarely more than 1 in. below the level of the symphysis pubis, and that in pregnancy the highest point of the head—highest, that is, from the horizontal couch—is rarely 1 in. above the horizontal level of the symphysis.

When the head is not in the pelvis at 36 weeks it may be due to the laxity of abdominal and uterine walls after frequently repeated pregnancies, in which case one can easily press the head into the pelvic cavity, or else to some degree of disproportion which is not necessarily a bar to a spontaneous labour. In this connexion I remember a primigravida with a diagonal conjugate of 3¾ in. and the fœtal head overriding the brim at the thirty-fourth week. She was examined with similar result several times during the next month and was admitted in labour the day before the date arranged for admission for Cæsarean section. The head was then in the pelvic cavity, and she expelled spontaneously a fine 8¼ lb. baby.

PELVIC CONTRACTION.

Having arrived at a diagnosis of pelvic contraction, the best means of delivering a living baby is to be sought. In the grosser degrees where the head cannot reasonably be expected to pass the only safe course is to arrange for Cæsarean section; in the lesser degrees the problem is more difficult. On the one hand all cases can be allowed to go into labour—under supervision—and when the head does not come down satisfactorily can be assisted either with forceps or by version, or Cæsarean section can be performed. On the other hand, the patients may be watched and labour induced prematurely in suitable cases; in those not suitable for induction Cæsarean section may be arranged.

If the first course be followed, there will be many emergency Cæsarean sections with the increased maternal risk attached thereto; forceps or version in emergency will be applied oftener and increase considerably the risk of stillbirth. Further, there being little need to keep the patients under close observation, they do not attend regularly, do not realise their danger and the need to report at hospital as soon as labour begins. Very naturally they desire to have the labour at home where they engage a midwife. A doctor is called in, and, sometimes after vainly trying to deliver, sends the woman into hospital, too late for anything but a craniotomy. If the other course is followed the Cæsarean sections will be less numerous, as they will be usually at a pre-arranged convenient time, and there will be few emergencies. The maternal risk from induction, properly carried out, is infinitesimal, and very much less than that in the forceps cases, &c., in the other series.

To obtain good results in induction cases requires prolonged and accurate observation, combined with the utmost delicacy of judgment as to the time chosen. The baby must be sufficiently well developed for its prematurity not to be a danger; that is, it should be within four, or in a few cases five, weeks of term. It must not be so large that natural expulsion is unlikely; the premature head is usually insufficiently ossified to withstand the forceps, and any obstetric interference considerably increases the intra-natal death-rate. Weekly observation of the relative size of the head and pelvis will indicate the best time for the induction: that is when, during the last month of gestation, the head is just rising out of or can no longer be pressed into the pelvis. The moulding which occurs during labour will permit of the engagement and transit of the head, now grown too large, in its natural shape, to remain in or to enter the pelvis.

The pelvis with contracted outlet has caused me the greatest difficulties and anxieties. I have never been satisfied with the accuracy of my measurements between the ischial tuberosities. The thick pad of tough fat which prevents discomfort when sitting on a hard surface equally prevents the definite marking of points from which to measure. At one time I believed that I had found a means, apart from vaginal examination, of recognising this type by an unusually large difference between the interspinous and intercristal diameters—say 2 to 2½ in., coupled with an external conjugate of 8 in. or more. While I am satisfied that this type of measurement signifies contracted outlet, I am equally satisfied that a pelvis with a contracted outlet may have the above measurements normal, and that vaginal examination is the only means of recognition. Radiography offers a promising field for investigation and confirmation. Further, I have an impression that this type of contracted pelvis is on the increase; at one time it was rarely noted, but now it is constantly being found. I do not think that the difference is due purely to fuller investigation.

Accurate measurement of the degree of contraction of the outlet being, so far as I am concerned, impossible, it may be difficult to decide sometimes whether natural delivery is probable or not. As a general rule a good idea may be formed after careful palpation of the pubic arch, ischial tuberosities and spines, and, as Whitridge Williams has shown, the amount of room between the tuberosities and the sacrum; the further back the sacrum the better chance of successful delivery. In a doubtful case one has to balance the risks of a stiff forceps delivery with unavoidable damage to the head, of a severe perineal tear—possibly through the sphincter requiring secondary repair at some future date—against those of a straightforward Cæsarean section, and I think there can be little doubt that the latter are the less.

Some patients come with a history of abnormality in earlier pregnancies or labours, and for some, of course, nothing can be done. I remember one patient who was sent because her first baby was an anencephalic. Malformations, of course, tend to recur in succeeding pregnancies, and are probably due to some inherent defect in the sex cells. This patient's gastro-intestinal disturbance was kept under control, and when she was examined late in pregnancy hydramnios and a baby with a very small head were recognised. I informed the midwife that I feared another anencephalic monster was present; however, she brought forth twins, of which one was anencephalic and the other normal. I think she never quite decided whether to be grateful for the one normal baby or to reproach me for not having given sufficient medicine to make both babies normal!

Difficult Labour.

Another group of cases report difficult labours, usually forceps, and sometimes craniotomies. Careful examination of the pelvis shows it to be of normal size, and no history of oversized babies is forthcoming. An isolated forceps delivery is frequently only evidence of a time-saving device on the part of the doctor, but repetition, especially when required in midwives' cases, necessitates closer investigation. The patient is frequently over 30 or even 40 years of age, and her tissues are flabby, anæmic, and fat. She is constipated and flatulent, and her abdomen is inclined to be pendulous; the uterine wall is lax, and, masked to a certain extent by the fat abdominal wall, allows easy palpation of the baby. The head can easily be pushed low in the pelvis. Prolonged manipulation of the uterine wall rarely stimulates contraction. The condition of inertia affects all her muscular system, voluntary and involuntary, and is confirmed by the low blood pressure, which may be below 100 instead of about 120 m.m. of mercury. The diagnosis points out the obvious treatment. Calcium, best given as the freshly prepared lactate, and pituitary extract, say, 0·5 c.cm., given intramuscularly night and morning, by raising the muscle tone and increasing the excitability of the uterus, have proved successful in a number of cases.

Similar treatment has proved of value in cases with repeated post-partum hæmorrhage in past labours when the circumstances have indicated inertia as the cause. When the hæmorrhage has been due to an adherent placenta the outlook is less promising; one can only be prepared to interfere during the third stage before the blood loss is serious. I have found neither medical treatment during pregnancy nor curetting, in the few cases where I have known it tried, to be of any value. Moreover, there is no reason to expect a more healthy endometrium to be regenerated from the fragments remaining after a curetting than from the decidual remains after labour. Further, I know of no evidence that the lesion is in the endometrium—the fault may quite possibly be in the chorion.

Syphilis in Pregnancy.

The incidence and diagnosis of latent syphilis is an interesting problem in pregnancy. Active syphilis is a reasonably straightforward affair as regards diagnosis, at all events, but one has so little to work on in latent syphilis. There is pretty general agreement that reliable evidence of syphilis can only be demonstrated in about 16 per cent. of stillbirths—the figure certainly is under 20 per cent. Obviously four out of five stillbirths are not syphilitic, and there is no justification for considering previous stillbirths to be evidence of syphilis. Abortions are even more confusing owing to the great difficulty, or even impossibility, of finding the spirochæte in known syphilitic cases. It has been suggested that this is due to the action of placental ferments on the spirochætes causing these to break up into biologically inactive granules which, on the removal of the influence of the ferments, develop into spirochætes again. The two objections I have to this view are: (1) That as this would imply the triumph of the resisting forces over the invader, what kills the ovum? (2) The ovum having been killed, and the placental ferments being at least a steadily diminishing quantity, why do the granules never blossom forth into spirochætes? A pathological report on a previous stillbirth, if positive, of course settles the question; a negative report is not quite so certain. One of my cases illustrates a difficult point. A patient came under treatment after an abortion and a still-birth. The Wassermann reaction (W.R.) was negative; she was treated by an iron tonic and had a healthy baby. The treatment was resumed in her next pregnancy, and she had, about term, a macerated stillbirth in which were found spirochætes. The most careful investigation revealed no support for recent infection, and I am still in doubt as to the sequence of events in this case.

The classical history of repeated abortions, premature and then full-term stillbirths, nonmacerated stillbirths, and neo-natal deaths is, in my experience, very rare. In a series of about 100 cases of latent syphilis which I investigated closely, I found the greatest variations in the history. Comparing syphiitic and non-syphilitic cases, the most suspicious eature—when it was present and nephritis could be excluded—was the repetition of premature stillbirths. This is not very satisfactory, and after all which of us is satisfied to await this or the classical sequence ?

As a further guide we have the W.R. I believe it to be, generally speaking, reasonably reliable (rather heavily qualified, I am afraid). One has had the W.R. reported negative during a pregnancy which terminated in a syphilitic stillbirth, and—even more unpleasant from my point of view—two cases where the blood was reported positive were sent to a venereal clinic for treatment; the blood was again examined, and this time reported negative and the patients told there was nothing abnormal to be ound. The remainder of the tale can be left to the magination.

Having arrived at a diagnosis of syphilis in any given case, the questions of treatment and prognosis arise. In women who are first seen during pregnancy, think the prognosis depends chiefly on the degree of infection and damage already present in the ovum. One can scarcely hope, even approximately, to estore to normal a syphilitic liver or placenta. In women who became pregnant during antisyphilitic reatment I found the prognosis uniformly good. One had to deal with these women before the V.D. linics were started; treatment by salvarsan and its mprovements and substitutes was out of the question xcept in isolated cases, and mercury was the standby. Hydrarg. cum creta tablets, 1 gr. t.d.s., with the necessary attention to oral hygiene, proved uniformly uccessful, and eventually I discarded the grey oil, which was resented by many patients.

NON-SYPHILITIC ABORTIONS AND STILLBIRTHS.

The patients with repeated abortions and stillirths without any evidence of syphilis present a ery difficult problem. Probably about one-fifth or ne-quarter are due to chronic nephritis, which may self be anomalous, as the following case shows. A oman, aged something over 30, was a second wife; er husband had had a healthy family by his first ife. The patient aborted regularly in the sixth month, the abortion being preceded by the appearnce of large quantities of albumin in the urine which, generally speaking, contained only a faint race or none, particularly when I came across her rst. In the later intervals the albumin did not isappear to the same extent and one came to the onclusion that she was a chronic nephritic; unforunately, she became pregnant again and developed fatal cerebral hæmorrhage. I was surprised at he extent to which the kidneys were affected. The est thing such patients can do is not to become regnant.

After eliminating the syphilitic and nephritic atients with repeated abortions, &c., we are still aced with about three-fifths of these cases where o obvious lesion can be found. One of the drugs ecommended is potassium chlorate, but I have not ad much experience of it. I have generally precribed iron in some form, the tinct. ferri perchlor. hen gastric conditions permitted, or some of the ilder preparations in other patients. When iron as failed I have usually found pot. chlorate also nsuccessful, and have sometimes found good results llow the administration of mercury, even where I as entirely satisfied that syphilis could be excluded. atterly I have usually given iron and mercury in hese cases. Naturally these patients tend to drift way after unsuccessful treatment; not many of hem can be followed through three or more pregnancies, and one cannot always find out what treatent has been adopted by one's predecessors in the tient's life-cycle.

HYSTERICAL FITS,

WITH SOME REFERENCE TO THEIR TREATMENT.*

By LEWIS R. YEALLAND, M.D. LONDON, ONT.,
M.R.C.P. LOND.,
PHYSICIAN TO OUT-PATIENTS, PRINCE OF WALES'S GENERAL
HOSPITAL; HONORARY REGISTRAR, WEST END HOSPITAL
FOR NERVOUS DISEASES.

FROM a psychological aspect it may be argued that the genesis of the neuroses, in whatever manner their manifestations may be expressed, is identical, and that therefore the separation of one particular group of symptoms from another, and the direction of attention to their treatment, is erroneous. This argument is logical enough, but in practice the suggestive factor is primarily associated with most, if not all forms of treatment, whether the suggestion is directed to a supposed cause of the disorder or, as in the method about to be described, to the removal of symptoms. Attention is here centred on that group of symptoms of the neuroses which is characterised by paroxysms or seizures and commonly termed the fits of hysteria.

The modern conception of the genesis of the neuroses, unlike the ancient supposition that hysteria was the outcome of wandering of the womb, cannot be repudiated in the light of anatomical facts. An example of this is to be found in that method of psychotherapeutic treatment of which the theory is, in brief, to ascertain the genesis of the neurotic symptoms, supposedly to be found in repressed desires too painful to be remembered—to release the repressed desire, then to allow it to become attached to the idea of the physician, and finally to release the energy expressed in the repressed desire and transfer it to a socially useful aim. It is claimed for this method, however, that proper technique does not admit of any suggestive factor. If this is true, the high degree of technical skill essential to carry out the treatment must confine the performance of such a process to those only who possess unusual advantages. Again, disastrous results, which are not uncommon, are attributed to defective technique; practical training is therefore rendered too dangerous to be undertaken. Moreover, the process of treatment occupies a long time and much patience is requisite in seeing the same individual day after day for years. Further, the penalty, expressed in distasteful memories, of symbolic interpretation involved in the reading of Freudian literature will tend to inhibit some from a further study of a subject which so closely simulates a pathological sexual curiosity. Finally, ignorance of the subject may persist and be the outcome of domestic cowardice revealed in a substitution of the flames for the bookshelf.

It may be safely stated that at present most patients suffering from paroxysms of the neuroses are treated during the paroxysm by the infliction of pain—supra-orbital pressure, strong faradism, &c.—but methods employed in treatment of seizures are of little value in prevention of a recurrence. The benefits of physic dispensed to combat the recurrence of hysterical fits lie, in all probability, in the suggestive factor arising from the administration of drugs. It would be difficult to discover a less burdensome aid to suggestion. The results of such treatment are in the possession of the experience of most physicians and need not be further discussed.

Clinical Observations.

The method that I have adopted to prevent recurrences of the fits of hysteria is based on the following clinical observations: (*a*) During a paroxysm the patient reacts to external stimuli. (*b*) A patient suffering from the disorder can be made to reproduce a seizure to order by a simple method. (*c*) The seizure thus produced corresponds in every apparent detail to the patient's previous attacks. (*d*) One type of seizure is constant in the individual and there is no change from one type into another. (*e*) During the paroxysm reproduced to order the patient can be made to realise that consciousness is retained from the beginning to the end of the seizure. (*f*) The patient, after realising that there is no loss of consciousness in the seizure, often becomes a good subject in whom the power of restraint or inhibition can be re-educated. (*g*) After a short course of re-education frequently no further attacks occur. (*h*) There are definite types of seizures which render classification possible.

---

* Read before the Section of Neurology, Royal Society of Medicine, June 14th, 1923.

During a hysterical attack a patient reacts to external stimuli—for example, the convulsion will subside on the infliction of pain if the latter is severe enough. Again, the attack becomes aggravated on the application of passive restraint, indeed, it would appear that the severity of an attack varies conversely with the degree of force exerted in attempting to hold the patient down. Such reaction to external stimuli would suggest that the degree of loss of sensibility is not deep during a seizure. The depth of insensibility would appear, from observation, to vary with the type of seizure rather than with the severity of the attack; the strongest stimuli being needed to rouse patients in whom tonic-like fits occur. Increase in the violence of the seizure on restraint would indicate that a seizure can be demonstrated to order, and this indication is strengthened by the occurrence of an attack when the patient is sufficiently urged to demonstrate a seizure.

In order to bring on a paroxysm in a patient subject to hysterical fits, considerable persuasion is sometimes needed and patients vary markedly in their willingness to produce an attack to order. Usually, at first, the patients will assert that it is impossible for them to demonstrate an attack in view of a lack of knowledge of its nature; however, persistence in urging the patient will result in feeble attempts being made by him to describe in words the nature of the attack. In cases where much difficulty is experienced in persuading the patient, methods may be employed to assist him to demonstrate the attack. For example, while standing he is commanded to close his eyes tightly and to make his body tense; while he lies on his back on a couch, he is ordered to raise his legs against the demonstrator's hands, which are placed on the patient's ankles. In the majority of cases an attack is readily reproduced by the latter method, but in some cases constant persuasion accompanied by determination is needed. It is, of course, essential to secure the patient's confidence, otherwise he may think he is being ridiculed.

Attacks thus produced resemble in every apparent detail the patient's previous attacks. This conclusion is arrived at by observing the seizure while the patient is waiting his turn for attention in the out-patient department of the hospital where seizures are not uncommon, particularly on the first visit, and afterwards persuading the patient to demonstrate a seizure to order. Again, friends of the patient who have observed previous seizures in the individual render further confirmatory evidence. Moreover, the patient will admit the similarity of the seizures after he has demonstrated an attack to order.

Although seizures vary in their character in different individuals, they always assume the same type in the particular individual, and there is no change from one type of seizure to another type. However, the severity of an attack in a given subject is rarely constant, and often mild attacks alternate with strong ones.

During a paroxysm produced to order the patient is constantly spoken to, and instructed to direct his attention to the general nature of the attack until it has subsided, after which he is asked to describe in words the various movements that were performed in the seizure. If his description appears to be hazy, the patient is again urged to reproduce an attack, which must be repeated until he has in general an intelligent conception of the nature of the movements. The patient is next asked to describe in detail by words the exact nature of the initial movements; if he cannot, an attack is repeatedly produced until he is able to do this. Finally his attention is directed to, and he is asked to describe the symptoms that preceded the initial movements. Some, on realising that they are conscious during a seizure, and that they have formed a clear idea of the nature of the attack from beginning to end, have no further seizures. But the majority of patients require a period of time during which re-education in their powers of inhibition must be undertaken. In order to accomplish this, my method is first of all to instruct the patient to lie on a couch and urge him to have an attack, during which time he is instructed to raise the lower limbs against the resistance of my hands placed on his ankles. After the attack has subsided he is ordered again to go through the same movements, but this time he is urged to relax the body during his attempts to raise the limbs and to inhibit the tendency to make the body rigid. It will be observed that although the patient is attempting to carry out the movement, the limbs are rigid and raised only a few inches from the couch in spite of the fact that pressure exerted on the ankles is so slight that the performance of the movement could not possibly be interfered with passively. It is advisable to persist with the patient until he is able to raise the legs at right angles to the trunk. When this is accomplished the muscles of the limbs are no longer rigid, and the patient becomes normally relaxed; the face no longer bears the expression of great strain, and there is reasonable ground to anticipate that the patient will successfully inhibit subsequent tendencies to seizures. The result is not always satisfactory, and if the previous methods have failed it is necessary to attempt to break down the resistance of the patient by inducing attacks frequently. For example, if he is subject to three or four attacks a day, attacks to order must be brought on in excess of that number and diminished from day to day and, if necessary, from week to week, depending upon whether or not there is a return of the paroxysm in the interval. It will be found that the patient will soon resent this treatment in view of its exhausting nature, and this indicates still more strenuous efforts to conquer the patient by producing even a greater number of attacks and so create in him an atmosphere of aversion to the attacks. The process, if successful, is usually not a long one, and the resistance of the patient breaks down after the second or third time. This method of treatment should not be undertaken in types 3, 6, and 7.

Types of Seizures.

Seizures which are the outcome of the neuroses present many types, and I have observed the following principal types: (1) An apparent momentary loss of consciousness, a faint; (2) a state of apparent coma lasting for hours, in which the pulse and respiration rates are normal; (3) a pseudo-tonic convulsion; (4) a pseudo-clonic convulsion; (5) a convulsion beginning in a pseudo-tonic contraction, followed by a pseudo-clonic contraction; (6) hystero-epilepsy; (7) attacks of uncontrollable laughing or crying in which the patient passes large quantities of urine; (8) other violent movements expressed in attempts to injure himself or those who attempt to restrain the patient by holding him down; (9) attacks of staggering. Paroxysms of the neuroses are not uncommon in epileptics.

Illustrative Cases.

Type 1.—An apparent momentary loss of consciousness is not uncommon in neurasthenic women whose symptoms are in the most part subjective. These patients complain of vertigo or fainting, in which they recognise their surroundings, but are unable to speak during the attack. Other conditions which cause vertigo and fainting must, of course, be eliminated before a diagnosis of hysteria is made. From the history of some of these patients petit mal may be suspected, and in the absence of witnessing an attack such a diagnosis is not infrequently made. The demonstration of the attack to order always confirms the diagnosis.

A woman of 45 years, the wife of a hairdresser, who resented he imputation that her husband was a barber, complained f "neurasthenia." She did not volunteer information egarding the occurrence of attacks, and when asked directly f she ever fainted at first affirmed that she did not have ysteria and was annoyed. Soon, however, she admitted aving attacks in which she "lost" herself for a moment, lways in the presence of her husband. After the threat hat she would leave the hospital and return to her home ather than submit to the indignity of demonstrating a eizure her confidence was ultimately gained and she was at ength persuaded to demonstrate the attack, in which she ecame rigid, clutched her right forearm with her left hand nd threw her head over the back of the chair on which she as sitting and began to respire noisily. The face became ightly cyanosed and her eyes were closed. The attack sted about 15 seconds. Through failure on the part of an experienced nurse to inhibit a laugh, the patient rose uickly to her feet, left the room indignantly, and has not nce returned to the hospital.

This illustrates that care must be taken to gain nd remain in the confidence of the patient, and the nfortunate results that ensue if hysterical manifesations are not treated with respect.

Type 2.—The simulation of coma as the outcome f the neuroses is, in my experience, not common in ospital practice. It may be argued that when atients assume a state of coma they should not be onsidered as hysterical, but it must be admitted that e patient at such a time is not normal mentally. he condition often occurs in young women who are naccustomed to the ordinary knocks of life. They e usually irritable.

A young woman of 22 years was to be married in a week's me. One night, just after dinner, her mother effected an trance into the consciousness of the patient's fiancé; in onsequence of which the mind of the latter was impervious r a moment to a question asked by the patient, who, eling slighted, retired from the room, to be further subitted to the indignity of a lack of recognition of her absence r nearly an hour. She was found on her bed fully dressed d could not be roused. It was reported that she was lseless but breathed slightly, and the diagnosis transitted over the telephone was cerebral hæmorrhage. On amining the patient in the presence of relatives she would t reply to any questions asked her, and no effort was made rouse her by force. After the relatives had left the room e suddenly asked angrily, "Who asked you to come re?" The patient's confidence was soon obtained, and e related the above-mentioned incident with much emotion. e patient has since become the mother of a healthy child d there has been no repetition of the attacks.

In such cases it is advisable not to acquaint the latives with the nature of the disturbance.

Type 3.—A tonic-like contraction of the whole body, e history of which simulates the tonic stage of an ileptic seizure, resembles clinically the first part of a stero-epileptic seizure, but does not progress further an a slight tilting forwards of the pelvis. The els and occiput are pressed firmly against the couch, e body is rigid, and the pelvis is raised from the rface of the couch. The face is flushed, the eyes sed tightly, and there is an expression of severe tress. During this pseudo-tonic state the breath is d. After half a minute to a minute the head turns her to the right or to the left and the muscles of the dy suddenly relax. The respirations then become y rapid and the patient either cries or laughs.

chorus girl, aged 21, fell from some badly constructed ps on the stage at a rehearsal and injured the back of her d and had a seizure. There was no scar or other evidence njury. She was unable the next day to take her part in performance in view of another attack which, when nonstrated to order, proved to be of the type described e. For two months the attacks occurred on an average twice a week, and for a week previous to my seeing her attack occurred every day. Considerable persuasion needed in this case to produce an attack to order. entually an attack was induced, after the patient was tructed to raise the limbs against passive resistance lied to the ankles. The patient's sister witnessed this ack as she had other previous seizures and confirmed that as similar in every detail to the other attacks. During seizure the patient was spoken to and replied to questions ed her with considerable effort. When the attack had sided she was questioned as to whether she was of the opinion that further attacks could be prevented with her own effort, and she replied in the affirmative, affirming that she did not recognise before that she was conscious during the attacks. She returned to her work in the chorus in a week's time, and did not fail to attend either rehearsals or performances. A month later on seeing the patient she said that there had been no return of the attacks. Two months later a seizure occurred in bed, and she volunteered the information that it was difficult for her to restrain the seizure during the menstrual periods; she deliberately had an attack, which she said she could have inhibited, but chose a time when it did not interfere with her work. She further stated that she was of the opinion that if she married it would not be necessary for her to have an attack, and asked advice regarding that matter. The patient has been married for nearly two years and there has been no recurrence of the seizures.

This particular case is chosen for illustration here because it can be regarded as favourable to psychoanalytical speculation; it may be asked what treatment is to be employed in cases where lack of opportunity renders marriage impossible? When the patient realises that the condition resolves itself into one of conscious choice, it would appear that there is no treatment except that which pertains to the practice of restraint on the part of the patient. These patients return to their duties, and although attacks sometimes occur in secret, their productive capacity is not interfered with and they become useful citizens.

Type 4.—Clonic-like fits are more common in men, and were in my experience the only type of hysterical seizure that occurred in soldiers in the recent war. A localised tremor is usually present, either in the fingers or the tongue, or there may be a blepharospasm. The attack, as a rule, comes on with some excitement or sudden shock, and often the banging of a door is sufficient to bring on a seizure. The tremor, which at first may be fine, becomes coarse, soon spreading all over the body; the patient falls down in a coarse generalised tremor and appears to be unconscious. As a rule he does not become violent unless he is passively restrained, when the convulsions become greatly aggravated.

A sawyer, aged 24, was unable to work for five years on account of seizures which began during an air raid in 1916, and one or more attacks occurred almost every day. There was a history in this case of mutism, which persisted for six months after the first seizure, to be followed by stammering. A partial right hemianæsthesia was made out. The patient responded to the suggestion to demonstrate an attack without much persuasion. This attack when fully matured consisted of violent clonic-like movements of voluntary muscles including the face, neck, trunk, and limbs. During the first attack demonstrated to order the patient did not respond to questions asked him, and after it had subsided he was unable to describe its nature. During the second attack produced to order the patient replied to questions during the first part of the attack, but when the movements became violent he did not answer questions put to him. When he was seen a week later he had had no attacks in the interval but complained of severe fatigue, the outcome of attacks produced during his former visit. He protested against further attacks being produced, but eventually submitted; in the next attack to order he was able to respond to questions asked him throughout, and was afterwards able to describe in detail the nature of the attacks. The following week, during an attack produced to order, he was instructed to relax himself as soon as the tremor became generalised by allowing his arms to fall loosely at his sides. A year after this treatment the patient had had no recurrence of the seizures, and he had been employed for nearly that length of time in a remunerative position. Sometimes, he said, he had a feeling of an attack impending, but by relaxing himself he was always able to prevent it.

It should be stated that this patient was of fairly average intelligence, in which case a good result is to be expected.

Type 5.—Seizures beginning in tonic-like contractions and followed by clonic-like contractions are not uncommon in men, and this type is most frequently mistaken for epilepsy. The patient suddenly becomes rigid when standing, his trunk is erect, and his head thrown back; he staggers backwards or sideways and finally falls, shaking all over. He may or may not injure himself when he falls. This type resembles in many details the one just described, but differs from it in an absence of the initial tremor and in the presence of a definite initial rigid state.

A grocer's assistant, aged 55, lost his wife, who died suddenly from heart failure. On hearing the news he collapsed and was thereafter subject to seizures, which, according to his local doctor's description, appeared to be correctly diagnosed as epilepsy. The attacks occurred on an average of once a day. When the patient was asked to describe in words the nature of the attack his eyeballs suddenly rolled upwards, his head was thrown back, and he remained rigid for about ten seconds. Then he began to stagger backwards and to shake all over and fell, bruising his right forearm. A nurse in attendance tried to prevent him from falling and on my instructions attempted to hold him down after he had fallen. With this restraint the violence of the shaking became aggravated. The attack began to subside with the removal of the restraint. With renewed passive restraint the movements again became violent, so that with repeated application of restraint the condition simulated status epilepticus, but it differed from the latter in the absence of a repetition of the rigid stage. When the restraint was removed altogether and the patient left to himself the paroxysm ceased and when he was instructed to rise to his feet he did so with difficulty and staggered. When seen next time the patient was urged to produce another seizure and with some persuasion he succeeded in demonstrating an attack which was in all respects similar to the preceding one. Again he fell and injured his right forearm. After the attack had subsided he was urged to demonstrate another seizure and resented the suggestion because of the pain in his right forearm; he submitted, however, but this time, when he fell he did not injure himself. On this occasion four attacks were induced and afterwards he was instructed to return in a week's time and informed that more attacks would be brought on if in the interval there was a recurrence. When he returned a week later, in spite of the fact of no attacks in the interval, two attacks were induced much to the patient's distress. The following week one attack was brought on, although there had not been a repetition of the seizures. The result was completely satisfactory. He was treated over a period of six weeks and there has been no recurrence of attacks.

Type 6.—Hystero-epilepsy or grande hysterie, as described in detail by Charcot and Richer, is not common in this country, and my experience of this type of hysteria is confined to four cases, only one of which was treated by the methods described here. The patients were all women. In view of the spectacular nature of the attack and the common idea that the state is partly epileptic, a record of observations made in one of the cases will be given. The attack was induced in the patient and witnessed by three colleagues.

An unmarried woman, aged 26, first associated herself with these attacks at the age of 18. The attacks occurred twice a week on an average. Of their nature, the patient claimed to be entirely ignorant, and she was therefore unable to give a description of them. She was on one occasion incontinent during an attack when it occurred in bed, and her tongue was sore after the attack. The patient was sent into a dressing room with the order to place herself on a couch there and to demonstrate the attack. The order was at first resented, but she was eventually persuaded, after a complaint that the couch was too narrow for the performance! The attack began by the patient throwing herself into a marked degree of generalised tension as if she were attempting to increase her stature by an apparent stretching of her neck and forcible plantar flexion of the feet, so that their plantar surfaces almost, but not quite, approximated to the surface of the couch, the legs being drawn tightly together. The arms were drawn close to the sides of the body, and they also appeared to be lengthened by over-extension of the wrists and fingers, the forearms being at the same time markedly pronated, so that the dorsal surfaces of the thumbs approximated to the surface of the couch. The eyes turned upward, the scleræ only being exposed; the face, almost from the beginning, became distorted in grimaces, and the cheeks and lips were firmly pressed against the gums and teeth. The patient's explanation of the movements of the face, at this stage, was to the effect that such contortions assisted in the production of saliva. Slowly the pelvis was raised from the surface of the couch with the assistance of her thumbs, and at the same time the head was gradually thrown backward. The soles of the feet now became approximated to the surface of the couch and were firmly pressed against it. The arms began to draw away from the sides of the body. Slowly the head retracted until the forehead rested on the surface of the couch. This was accomplished by the patient tilting the pelvis more and more ventral by drawing the feet under the trunk towards the head until finally the forehead and the heels became about approximated. The face was by this time intensely cyanosed, and the front of the neck appeared markedly swollen, the cyanosis being due to partial suffocation in view of the position of the head. Respirations became quickened and the patient could be seen to protrude blood-stained foam between her teeth by forcibly pressing the tongue against them. The arms assumed a position at right angles with the trunk and athetoid-like movements appeared in the fingers. The explanation given by the patient of the position of the arms was to the effect that it helped her to balance. When the arms were forcibly moved in all directions they appeared to be wax-like, and the patient's equilibrium was not upset in these movements. The arched body was extremely tense and supported without difficulty strong pressure on the abdomen. In this state of arc de cercle the patient answered questions asked her by others in the room, but to the question, "You do not know what I am saying?" asked by a colleague, who at this stage came in, she did not reply. The patient remained in this position for ten minutes, and clonic-like movements occurred for a few seconds as the body tilted over to the right side; gradual relaxation from superextension slowly took place, until the patient once more assumed a relaxed dorsal position. The plantar surfaces of the feet on the couch together with the forehead, during the severe state of opisthotonus, formed a tripod, and seemed to be sufficient to support the body in that position. With complete relaxation there was extreme fatigue. In the course of this attack there was no appearance of the third and fourth stages as described by Charcot, in which dramas are enacted and a period of delirium occurs. The treatment of the seizure consisted in demonstrating to the patient that she was not, as she supposed, unconscious during the attack, but rather, fully alive to every detail. When the patient returned in a fortnight she reported the occurrence of one paroxysm when she was in bed. On being told that the attack could be controlled the same as walking could be controlled, she admitted that the attack had been deliberately induced by her because it produced a "pleasant sensation." By degrees she chose to inhibit the impulse to produce the sensation, but not altogether.

The attacks have been reduced in the last two years from several a week to about the same number a year, and the paroxysms occur now when she is alone and they do not interfere with her duties.

Type 7.—Paroxysms of uncontrollable laughing or crying in which large quantities of urine are passed in my experience only occur in women who practise uncleanliness with themselves. Attempts to induce an attack in these cases are, of course, to be avoided. Such patients are benefited by hard manual labour on farms.

Type 8.—Seizures which may be described as violent movements in which the patients tear at their clothing, attempt to injure those who make an effort to restrain them, and in the event of nobody attempting to do so, will pull at their own hair and injure themselves by scratching or biting their arms, are not uncommon in both sexes, but are much more frequent in females. The movements are very grotesque, and the patients in their agitation will expose themselves, shout, and call out for a friend. The condition is sometimes difficult to diagnose from manic depressive insanity at first sight. The seizure in no way resembles epilepsy.

A woman, 30 years of age, suffered from this type of attack for a year, and seizures occurred on an average of three times a week. The first paroxysm began after she was told that she had contracted syphilis from her husband and while waiting for an intravenous injection of novarsenobillon. The attack was very violent, and she was held down by fellow patients in the out-patient waiting-room. A week later, when she was urged to demonstrate an attack, she began it by turning her trunk and head violently from left to right. She threw out her arms and called for her mother, and knocked her head against the floor. The hair soon became dishevelled, and she began to tear at her clothing, shouting louder and louder. She was firmly ordered to rise to her feet, which she did, and complained that her arm was numbed. She made a promise to control these attacks, and there has been no recurrence for six months.

Type 9.—Attacks of staggering, which, according to the subjective evidence gained from the patient would suggest petit mal, are often preceded by globus, palpitations, or disagreeable sensations in the abdomen. The attack may occur in the absence of these symptoms or one or all of them may be present.

A joiner, aged 48 years, came over giddy when working on a building in a safe part and lost his "senses" but did not fall. There were no signs of organic disease, and other causes of vertigo were eliminated before arriving at a diagnosis. When he was asked to demonstrate an attack he said he became giddy and lost himself completely, but could not demonstrate the nature of the attack. After much persuasion and after he had paced up and down the room in his attempt to produce an attack for several minutes, he suddenly began to stagger sideways and to the right, reaching out his right hand for the purpose of supporting himself at a table. The patient said he was giddy, and that the attack which had just occurred was not the outcome of efforts to demonstrate the attack. He was at once ordered to produce another seizure, a suggestion to which he almost immediately responded. The attacks were repeated several times, and he was finally convinced that he was completely conscious during the attacks, and that it was in his power to bring on an attack at any time as it was under the control of his will. This resulted in a subsidence of the attacks for eight months; since that time there is no note made of his case.

Epileptics may be subjects of paroxysms of the neuroses. A hysterical attack may immediately follow an epileptic seizure, or the former may bear no relation to the latter as far as its occurrence in time is concerned. Again, the occurrence of petit mal, grand mal, and paroxysms of the neuroses are not uncommon in the same individual. The conditions must be treated separately. These patients should be given luminal, one and a half grains, three times a day in addition to the treatment for the hysterical condition.

Conclusion.

A diagnosis between hysterical fits and epilepsy is rendered difficult and sometimes impossible if no seizure is witnessed. Babinski and Froment were able to reproduce a hysterical fit in a subject by suggestion aided by electricity. Electricity is certainly not needed to reproduce a hysterical fit, and it is doubtful if extraneous suggestion is needed. I have frequently seen hysterical fits reproduced while the patient has attempted to raise the lower limbs against passive resistance, no order being given and no comment made other than "raise the lower limbs." I have the permission of an officer who was on duty at the recent Trooping of the Colours to state that 5 per cent. of the rank and file, after standing in a rigid state of attention, fell out in a fit in the course of the first ten minutes of the performance. An attack seems always to follow a certain state of tone of the muscles, which is created by simultaneous contraction of agonists and antagonists. Clonic-like movements occur in many neurasthenic individuals subjected to the same test, and in them there is the same distressed facial expression. No wholesome effort is made to overcome the passive resistance as in the healthy individual, who usually either succeeds or in his attempt to do so sits upright. This test is, I believe, of considerable diagnostic value, and may be as easy or as difficult to elicit as a plantar reflex.

The treatment which has been considered in these cases resolves itself into the removal of symptoms, and in the selection of 100 cases for the purpose of determining results, an equal number of each type of paroxysm has been chosen as far as that has been possible. The record has been brought up to a recent date, and the period of freedom from the attacks varied from five years to six months. The percentage of recoveries from attacks is about 60. Types 3, 6, and 7 materially diminished the number of apparent "cures," but in them improvement was observed in the marked reduction in the number of seizures and in the fact that the attacks occurred when the patients were alone.

Two of the reported cases were patients at Queen-square, and I have to thank Dr. Gordon Holmes and Dr. Hinds Howell for permission to publish them.

THE ANTICOAGULATING ACTION OF THE ARSENOBENZOLS ON BLOOD.

By THOMAS ANWYL-DAVIES, M.B.,
B.S. LOND., M.R.C.S.,
VENEREAL DISEASES DEPARTMENT, ST. THOMAS'S HOSPITAL
AND
JOHN MELLANBY, M.D. CAMB.,
PROFESSOR OF PHYSIOLOGY, LONDON UNIVERSITY.

Flandin and Tzanck have described in THE LANCET [1] the anticoagulating action of the arsenobenzols on blood. They state that (1) the coagulation time of blood from an individual who has received an intravenous injection of arsenobenzol may extend from 30 minutes to 24 hours or longer, and (2) the state of incoagulability, as shown by repeated samples of blood, may continue for a period varying from several hours to several days. The authors deduce from their observations the necessity for considering whether a patient is under treatment with arsenobenzol before submitting to surgical procedures. They also suggest that arsenobenzol is superior to citrate as an anticoagulant for blood, since small quantities of it do not modify the volume or quality of the constituent elements of blood. They do not discuss the mechanism by which arsenobenzol acts as an anticoagulant, except to state that the corpuscles and platelets are not modified in form or number and are not agglutinated. In view of the extensive therapeutic use of the arsenobenzols we have determined in detail the anticoagulating action of this type of compound on blood. We find that the addition of one part of arsenobenzol to a thousand parts of blood prevents the coagulation of blood in vitro; that a similar quantity injected intravenously into rabbits prevents coagulation for a brief period of time (less than one hour) after which normal coagulability returns; and that therapeutic doses, used in clinical cases, have practically no effect on blood coagulation except to a small degree after long courses of administration.

In the following description we consider the anticoagulating action of the arsenobenzols when (*a*) added to blood in vitro, (*b*) injected intravenously into rabbits, and (*c*) used in therapeutic quantities on man.

(*a*) *Experiments in Vitro.*

The coagulation of blood in vitro is prevented by the addition to it of 0·1 per cent. arsenobenzol. This anticoagulant action of arsenobenzol is exerted entirely on the last phase in blood coagulation—that is, on the action of thrombase on fibrinogen whereby the formation of fibrin is prevented or delayed. The following experimental results (Table I.) show this inhibitory action of neosalvarsan on the coagulation of oxalated plasma by thrombase (fibrin ferment).

TABLE I.

Oxalated plasma.	Neosalvarsan 1 per cent.	Thrombase.	Coagulation time.
2 c.cm.	0 c.cm.	0·6 c.cm.	4 mins.
,,	0·1 ,,	,,	11 ,,
,,	0·2 ,,	,,	16 ,,
,,	0·3 ,,	,,	50 ,,

Table I. shows that the time of coagulation of plasma by thrombase was extended from 4 to 50 minutes by the addition of 0·1 per cent. neosalvarsan.

The following experiments show that the enzyme thrombase is not affected by neosalvarsan. A solution of thrombase was incubated with varying quantities of neosalvarsan for 30 minutes, and the coagulating activities of the resulting solutions were then determined (Table II.).

During the incubation period of 30 minutes the neosalvarsan had full opportunity to destroy the thrombase. The coagulating activities of the mixtures when tested on oxalate plasma showed that no destruction had taken place (Table III.).

---

[1] French Supplement, 1922, ii., 1177.

TABLE II.

Thrombase.	Neosalvarsan 1 per cent.	—
1 c.cm.	0·3 c.cm.	(X)
"	0·2 "	(Y)
"	0·1 "	(Z)

TABLE III.

Oxalated plasma.	—	Coagulation time.
2 c.cm.	0·6 c.cm. (X)	6½ mins.
"	" (Y)	4½ "
"	" (Z)	4 "

The slightly increased time of coagulation with (X) and (Y) compared with (Z) was due to the additional quantities of neosalvarsan contained in these fluids.

It is evident that neosalvarsan does not destroy thrombase. Therefore the inhibitory effect of this compound on blood coagulation must be intimately associated with its action on fibrinogen. Probably the neosalvarsan unites directly with the fibrinogen, and the complex thus formed is less readily coagulated by thrombase. This hypothesis is supported by the fact that all arsenobenzols do not affect the coagulability of the blood. Thus, neosalvarsan (German), sulfarsenol, and novarsenobillon are equally effective in preventing blood coagulation, but stabilarsan has no such anticoagulant action. Stabilarsan is a glucose compound of arsenobenzol. It is probable, therefore, that that portion of the arsenobenzol group which combines with glucose is also responsible for the combination of the arsenobenzol with fibrinogen. In this connexion it is of interest to observe that inorganic compounds of arsenic do not affect the coagulation of blood. Consequently the combination of the arsenic with the fibrinogen must be due to the particular grouping which is common to the arsenobenzols and which can combine with glucose as readily as with fibrinogen. The fact illustrates the rôle of the subsidiary groupings in determining the physiological action of any compound.

(b) *Experiments in Vivo.*

The anticoagulant action of the arsenobenzols when injected intravenously into animals is of the same order as that observed in test tube experiments. Thus the intravenous injection of neosalvarsan, sulfarsenol, or novarsenobillon into animals to the extent of 1 part per 1000 parts of blood immediately delays or prevents the coagulation of the blood, whilst a similar injection of stabilarsan has no effect on its coagulability. But, whereas Flandin and Tzanck describe the anticoagulant action as persisting for periods of time varying from several hours to several days, we find the effect extremely transitory. The results we obtained are illustrated in the following experiments:—

Rabbit 1.—1 cm. neosalvarsan (10 per cent.) was injected into the marginal vein of the ear = 0·1 per cent. in the blood. Samples of blood were taken from the ear vein after varying periods of time (Table IV.).

TABLE IV.

Sample of blood.	Coagulation time.
Before injection	2 mins.
10 mins. after injection	No coagulation in 24 hours.
60 " " "	2 mins.

Other experiments showed that the normal coagulation time was restored within 30 to 45 minutes after the intravenous injection of the neosalvarsan.

Rabbit 2.—3 c.cm. of neosalvarsan (10 per cent.) into the marginal vein of the ear = 0·3 per cent. in the blood. As before, samples of blood were taken from the ear vein after varying intervals of time (Table V.).

TABLE V.

Sample of blood.	Coagulation time.
Before injection...	3 mins.
10 mins. after injection	No coagulation.
45 " " "	"
60 " " "	"
90 " " "	2 mins.

Thus the coagulability of the blood returned in 90 minutes, although the amount injected would correspond to an intravenous injection of 10 g. into a normal man. With the return of coagulation an increased coagulability (positive phase) is often observed, indicating some reaction of the organism against the anticoagulant circulating in the blood.

Experiments were made to determine whether the arsenobenzols readily produced cumulative effects on the coagulability of the blood. The following result illustrates this type of experiment:—

Rabbit 3.—2 c.cm. neosalvarsan (10 per cent.) into the marginal vein of ear. Blood coagulation was inhibited for one hour, after which time normal coagulability returned. A second injection of 2 c.cm. of the neosalvarsan solution was now given. The blood became non-coagulable, but regained its coagulability in 75 minutes. A third intravenous injection of 2 c.cm. neosalvarsan (10 per cent.) was administered; 90 minutes after the third injection the coagulability of the blood became normal.

It is evident from experiments of this order that there is no marked tendency for the arsenobenzols to accumulate in the blood and thereby to produce cumulative effects comparable to the coagulation times described by Flandin and Tzanck.

Rabbit 4.—2 c.cm. stabilarsan (10 per cent.) into the marginal vein of ear. No effect on blood coagulation either immediately or half an hour later.

These observations indicate (1) that stabilarsan does not affect the coagulability of the blood in vivo, and (2) that the glucose is not split off from the salvarsan before absorption from the blood.

(c) *Clinical Observations.*

The preceding experimental work shows that the addition to blood of some of the arsenobenzols to the extent of 0·1 per cent. inhibits coagulation not only in vitro but also in living animals. But when the arsenobenzol is injected into animals the effect on the coagulability of the blood passes off extremely rapidly, probably owing to the absorption of the arsenobenzol by the tissues and its separation from the fibrinogen of the blood. The quantities of the arsenobenzols injected intravenously into the experimental animals were, however, considerable, compared with the therapeutic doses used for clinical cases. Thus, 1 c.cm. of a 10 per cent. solution of neosalvarsan injected into a rabbit corresponds with an injection of 3 g. into a man, a quantity greatly in excess of the usual maximum dose of 0·9 g. Corresponding with this fact we find that the intravenous injection of therapeutic doses of the various neosalvarsans has practically no effect on the coagulability of the blood of human beings, the maximum dose of 0·9 g. giving a concentration of only about 0·02 per cent. neosalvarsan in the blood.

The effects on the coagulability of the blood of the various organic arsenical compounds immediately after intravenous injection are illustrated by the following cases (Table VI.):—

TABLE VI.

—	Coagulation time—	
	Before injection.	10 mins. after injection.
A. Neosalvarsan (German) 0.45 g	2 min. 10 sec.	2 min. 10 sec.
B. " " "	2 " 25 "	2 " 45 "
C. " " "	2 " 45 "	3 " 5 "
D. " " "	3 " 0 "	3 " 25 "
E. Sulfarsenol 0·6 g.	3 " 40 "	3 " 10 "
F. Stabilarsan "	2 " 30 "	2 " 20 "
G. " "	3 " 30 "	3 " 40 "
H. " "	2 " 10 "	2 " 10 "

It is evident from the above figures that the intravenous injection of therapeutic quantities of the various arsenobenzol compounds has practically no effect on the coagulability of the blood. Thus the coagulation figures for stabilarsan (which does not effect the coagulability of blood) before and after injection do not differ in any marked degree from those given by neosalvarsan and sulfarsenol, both of which entirely prevent blood coagulation in vitro. Again, in some cases (F and E) the coagulability is slightly increased; in other cases (B, C, D, G) there is a small delay; and in the remainder (A and H) there is no change.

The effect of repeated injections of the arsenobenzols on the coagulability of the blood was determined. Although experiments on rabbits for short periods of time gave no indication of any cumulative effects of these compounds on the blood, yet it appeared possible that such effects might arise in human beings, especially in cases of long-continued administration. The following coagulation times were obtained before and after an intravenous injection of arsenobenzol in cases which had undergone prolonged treatment (Table VII.).

TABLE VII.

—	Coagulation time—	
	Before injection.	10 mins. after injection.
K. 6 previous injections of neo-salvarsan	2 min. 45 sec.	3 min. 5 sec.
L. 13 previous injections of neo-salvarsan	3 " 0 "	3 " 25 "
M. 20 previous injections of novarsenobillon	2 " 25 "	2 " 45 "
N. 50 previous injections of various arsenobenzols ..	2 " 20 "	3 " 30 "

Except in Case N the results offer no evidence that the arsenobenzols accumulate in the blood and inhibit its coagulability even after an extensive series of intravenous injections. Even in Case M the delayed coagulability is small and does not bring the coagulation time outside the normal limits.

Summary.

As a result of our investigations we find that some of the arsenobenzols (neosalvarsan, sulfarsenol, novarsenobillon), when added to blood to the extent of 0·1 per cent. prevent its coagulation. This inhibition is due to the action of the arsenobenzol on the fibrinogen, probably by direct combination with it. The combination of the arsenobenzol with fibrinogen depends upon the organic grouping, since arsenious oxide has no effect on the coagulability of the blood, nor does arsenobenzol combined with glucose (stabilarsan) alter blood coagulation. Arsenobenzol, 0·1 per cent., inhibits the coagulation of blood not only in vitro but also in vivo. But in the animal body the inhibition of coagulation passes off within an hour, probably owing to the passage of the arsenobenzol from the blood into the tissues. Therapeutic doses of the various salvarsan preparations intravenously injected into men or women have practically no effect on the coagulability of the blood, since these quantities fall far below the minimum amounts required to produce fluid blood. Further, the arsenobenzols do not appear to accumulate in the blood and thereby effect its coagulability, since even after prolonged courses of administration the coagulability of the blood remains normal. Hence, previous treatment with arsenobenzols, from the point of view of the blood coagulability, need not be seriously considered when surgical operations are in question.

We are indebted to Colonel L. W. Harrison for permission to determine the action of the arsenobenzols on the coagulability of the blood in clinical cases.

MARRIAGE, PREGNANCY, PARTURITION, AND TUBERCULOSIS.[1]

BY E. WARD, M.D. CAMB., F.R.C.S. ENG.,
TUBERCULOSIS OFFICER, SOUTH DEVON.

THE importance of the question as to whether a tuberculous woman should marry need not be laboured. To answer it we must know what are the risks, if she does marry, to herself, her children, and her husband. Search in the literature of the subject, extensive though it be, does not provide a sufficient answer. We find series of cases, leading to different conclusions; the results of tuberculin injections, contradicted by others, and statements by great men. The text-books again do not help us much. Osler writes: "Child-bearing increases the risks from tuberculosis *enormously*," and quotes Dubois as follows: "If a woman threatened with phthisis marries she may bear the first accouchement well, a second with difficulty, a third never." But opposite opinions are stated with equal emphasis. I have heard more than one experienced practitioner express the view that marriage and child-bearing always benefit tuberculous women. By investigation of the material which comes to my notice I have attempted to throw further light on this difficult problem, and am driven to conclude that, as often happens in controversies, both schools are right, and both are wrong. In many respects my conclusions agree with those published by Fishberg.[2] First let me cite two cases illustrating a type not infrequently seen.

A woman was under treatment at 26, during three years, at a public dispensary, for tuberculosis of the lungs; she then married and bore 10 children. Marriage improved her health, as also did the first childbirth; of the other confinements some have made her worse, some better, and by some she was unaffected. To-day (at 54) she remains much as when she married; not many physical signs in the chest, a little daily sputum, in which tubercle bacilli have recently twice been found. Of her children three died from tuberculosis, three are alive but tuberculous, two have died from unknown causes, two I would pass as negative.

A woman, now aged 47, was from 16 to 18 confined to her room because of pulmonary tuberculosis. She then gradually got about again, married at 24, and has been better since. Occasionally she was worse after parturition, at other times better, mainly unaffected. Of her 11 children, three are tuberculous, and have all been in sanatoriums; four are "suspect," one dead, three are alive, but as yet unexamined by me.

For nearly three years I have been trying to collect evidence of the risks of matrimony to tuberculous women; the work is not nearly complete, and is imperfect in many respects. Inquiries are afoot which may double the number now to be quoted, but I do not think the conclusions will be materially different. Nothing elaborate is aimed at; only to say roughly whether the patient is made better or worse, or left unaffected by marriage, pregnancy, parturition, or lactation. The condition of the children was also investigated. The information was obtained by personal observations in some cases, in others by questioning, cross-questioning, and re-questioning on different occasions; the answers being checked, where possible, by collateral inquiries from relatives, friends, or the practitioner in attendance. When in doubt it is safe to say "unaffected." Only major tuberculosis is considered. There are several difficulties, the chief being to decide if the deterioration in health is due to an exacerbation of tuberculosis or to some other cause. Of the latter the principal are vomiting in pregnancy and perineal or uterine injuries and displacements after parturition; by inquiry these can usually be differentiated from tuberculosis if their existence is borne in mind. The results of hæmorrhage are not so important, as the patients often recover rapidly; if not, this may itself lead to an exacerbation of the disease. There are many tempting side tracks, but the main road will be followed, and for the sake of brevity and clearness the results are expressed in percentages.

---

[1] A paper read before the Tuberculosis Society.
[2] Fishberg: Pulmonary Tuberculosis, 1922.

Marriage.

The effect of marriage alone in 125 tuberculous women was: 60 per cent. unaffected, 26 per cent. better, 14 per cent. worse. Lately I have begun to include men, but only 23 have been investigated so far; of these 70 per cent. are unaffected, 26 per cent. better, 4 per cent. worse. Thus tuberculosis is unaffected or is improved by marriage in about 90 per cent. of tuberculous women.

Bearing in mind the fact that 15 to 20 per cent. of patients may be expected to deteriorate in any period of one or two years we must conclude that marriage has, if anything, a beneficial effect on tuberculosis.

Pregnancy.

Out of 423 pregnancies in 237 women, 53 per cent. had no effect, 16 per cent. improved the patients, 31 per cent. made them worse. The clinical *onset* of disease occurred during pregnancy in about 4 per cent. of women, and of these less than half terminated fatally. Some cases are remarkably improved by pregnancy, others go to pieces, but about 70 per cent. are better or unaffected. Unluckily it is impossible to consider pregnancy apart from parturition.

Parturition.

Out of 442 labours in 240 patients, 32 per cent. left the patient unaffected, 19 per cent. made her better, and 49 per cent. worse.

The onset of disease occurred after parturition in 17 per cent. of patients, of whom nearly one-half died. If we add the pregnancy onsets it gives us 21 per cent. Apart from these onset cases, which naturally attract notice, and have considerably influenced writers on the subject, only 2 per cent. of women died as the direct result of an exacerbation caused by child-bearing; so that parturition is likely to make pre-existing tuberculosis worse, but unlikely to make it fatally so. The worst are the onset cases, which cannot be foreseen. Yet there are instances (19 per cent.) where parturition has a beneficial influence, sometimes strikingly so. A patient with chronic phthisis, almost an invalid, may suddenly pick up after the first baby, and become the mother of a large family. Sometimes we find a patient better during pregnancy, worse after the confinement, less often the reverse; the patient goes downhill rapidly during pregnancy but picks up wonderfully afterwards, although she has to look after a child. We must not underrate the mental factor in these conditions. A study of resistance to this disease in pregnancy, and after childbirth, may yet throw welcome light on the mechanism of immunity.

Miscarriage.—I have not yet fully investigated the result of miscarriages, but of 31 of these 14 (47 per cent.) had no effect, 1 (3 per cent.) improved the patient, 16 (50 per cent.) made them worse. The onset occurred after miscarriage in four of these women (12·5 per cent.), of whom one-half died. The value of induced abortion in tuberculous women seems very questionable.

Lactation.

Out of 331 cases investigated, in 197 the mother breast-fed the child for a period from a few weeks to over three years, but in only 2–3 per cent. did lactation appear definitely to cause deterioration. The patient became gradually worse long after parturition, but before lactation ceased. I expected the effect of lactation to be much more marked, but there are many points to be considered here. Nature takes good care of us in this respect; a woman too ill to suckle is generally unable to do so. Lactation may be exhausting, but it may prove even more exhausting to get up at night to heat bottles and to deal with a child made more fretful, perhaps, by artificial feeding. And the amount of nourishment withdrawn in the first six weeks is not large. There are also other more subtle considerations.

The Children.—Of the offspring from the labours already considered, 372 were traced and 290 investigated personally. Of these 45 per cent. were negative, 34 per cent. tuberculous, of whom one-quarter died of the disease; 21 per cent. were suspect. Among the children unexamined by me 42 per cent. were dead from causes unknown or other than tuberculosis. We include with these most cases where the death of infants was attributed to "consumptive bowels." Compare with this the examination of 82 controls—that is, contacts of non-tuberculous persons; 87 per cent. of these were negative, 5 per cent. tuberculous, 8 per cent. suspect.

Out of 177 children breast-fed by tuberculous mothers 35 per cent. were negative, 31 per cent. tuberculous, of whom one-fifth died, 15 per cent. were suspect, 15 per cent. unseen by me, and 4 per cent. dead from causes unknown. Among 116 bottle-fed children 32 per cent. were negative, 25 per cent. tuberculous, of whom one-fifth died, 14 per cent. suspect, 14 per cent. unseen by me, and 15 per cent. dead from unknown causes. There are pitfalls, no doubt, but on the whole the increased risk to the child from breast-feeding under these circumstances seems negligible.

As concerns the husband, space does not allow the discussion of conjugal tuberculosis here. I look upon it as certain that the husband will be infected sooner or later if not congenitally immune, or with a smouldering infection of his own.

Summary.

Summing up, we find that a tuberculous woman loses nothing by marriage alone. It is unlikely to affect her either way; if it does affect her it is more than twice as likely to improve her condition as to cause deterioration. Pregnancy and parturition are likely to make her worse; there is, however, only a 50 per cent. chance of this against a 19 per cent. chance of improvement. But the children are seven times as likely to be tuberculous as those of healthy people.

As to the advice which may be given to a patient about to marry: patients who ask for such advice will not take it unless it coincides with their wishes. If the doctor says "Do not marry," and consciously, or subconsciously, the young couple are anxious not to marry, they may abide by his decision, but not otherwise. Often enough the only result of such advice is a more hasty marriage. The best way to prevent an undesirable union is to procrastinate. The advice should be "wait," expressed in as many words as may be considered appropriate to the occasion. Each case must, of course, be considered on its merits from all points of view. My figures, moreover, apply only to the poorer classes. I am now making an attempt to secure figures from better class patients.

To relatives percentages may be given. The chief risk is to the children, and this should be emphasised. A woman of marriageable age with major tuberculosis *should not bear children.* To counterbalance the loss of gratification of the maternal instinct must also be placed the risks of deterioration to the patient. Finally as to lactation. If milk is available it is wise for a tuberculous woman to breast-feed the child for six weeks certainly, longer in many cases, but never longer than eight months, and always with precautions if she is infective.

Is it possible to estimate the risks of a tuberculous inheritance as contrasted with the risks of infection by a comparison of the children of closed surgical and open pulmonary cases? I cannot yet say, but will certainly make the attempt, although if Piéry's[3] observation be confirmed, that the sweat of patients with closed surgical tuberculosis gives positive inoculation results in guinea-pigs in 30 per cent. of cases, the difficulties will be well-nigh insuperable.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT PORTSMOUTH.

(Continued from p. 518.)

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

WEDNESDAY, JULY 25TH.

AT the opening session, with Mr. VICTOR BONNEY presiding, Mr. A. W. BOURNE opened a discussion on

Acute Salpingitis.

He said that his paper was confined to the treatment of acute suppurative salpingitis with pelvic peritonitis. Catarrhal salpingitis never required more than the simplest medical treatment.

Clinical Description.—This was essentially an attack of acute suppurative pelvic peritonitis, with a background of genital symptoms due to acute suppuration in one or both Fallopian tubes. The symptoms were: acute pain, tenderness, and rigidity of the hypogastrium. Moderate fever. Later there are distension of the lower abdomen, constipation, and sometimes vomiting and painful micturition. In addition there are uterine hæmorrhage, leucorrhœa, and vaginal tenderness. No definite swelling can be made out, owing to the softness of the enlarged tube and the pain of examination.

Aim of Treatment.—Mr. Bourne said that the cardinal lesions requiring treatment are: (*a*) Suppurative inflammation of the tubes, and later of the ovaries; (*b*) suppurative pelvic peritonitis. These two conditions were inseparable and could not be regarded independently. The object of treatment must be: (1) to arrest the acute disease and prevent its extension to the abdominal cavity proper; (2) to prevent the formation of chronic sequelæ; (3) to restore the tube to normal function. It was very rare for the peritonitis to extend to the abdominal cavity proper, except after full-term labour, when the tube is an abdominal organ. Pyosalpinx, chronic thickenings, adhesions, &c., produced chronic semi-invalidism with relapses of acute symptoms. Bilateral salpingitis was followed by sterility.

Pathology of Acute Salpingitis.—Sections were shown on the epidiascope demonstrating Fallopian tubes in various stages of inflammation. The lumen was at first distended with pus and the plicæ were very œdematous. In the early stages the epithelium was in a fair condition. In a few places there might be desquamation. At a later stage the lumen was clear of pus, the plicæ were still œdematous, and traces of newly-formed fibrous tissue could be seen. The epithelium was still in good condition, but the ulceration was more marked. A later stage was shown when the lesion was becoming chronic. Epithelium was poor, and the commencement of adhesions was noticeable. The plicæ were still distended with exudate. The fourth stage was that of natural resolution. There was a large amount of fibrous tissue in the plicæ, while the epithelium, though intact, showed a tendency to heaping up. It was unlikely that such cells retained their cilia. The conclusions to be drawn were: 1. That in spite of a very acute salpingitis the epithelium is remarkably resistant in the early stages, and only shows partial desquamation. 2. That after the acute phase has passed off most of the epithelium surface is intact, but what lesions there are are likely to develop adhesions. 3. Plical adhesions may be very extensive in the tube, cutting up its channel into a number of diverticula which probably harbour infection and predispose to ectopic gestation.

Treatment.—Expectant and medical methods would usually lead to a subsidence of the acute symptoms and the patient "recovered." She was left sterile and the development of chronic salpingo-oöphoritis or pyosalpinx was only a matter of time. If acute salpingitis was capable of resolution as a result of medical treatment, how did chronic interstitial salpingitis arise? The commonest operation on the tube was for these chronic inflammatory conditions and the great frequency of this disease was an indication of the ordinary sequel of the disease in an acute form. Medical methods might suffice to nurse the patient through the acute stages, but she was left with a chronic inflammatory focus in the pelvis and the prospect of years of pain, menorrhagia, and sterility. The ideal treatment was to arrest the destructive inflammatory process before the desquamation of the tubal epithelium and the formation of intra-tubal adhesions and the diverticulæ and sealing of the ostium had occurred. It was therefore important to operate as soon as the disease was diagnosed. The sooner the abdomen was opened the easier it was to restore tubal function by arresting the destructive suppurative processes. The chief objections to operation in the acute stage were: (1) that it is usually "unnecessary"; (2) that it may be dangerous in spreading infection. The first objection had already been discussed and it had been shown that surgery is necessary for the treatment of chronic tubal disease. The second objection used to be urged against operation for acute appendicitis before the fifth day. It was no more valid when applied to salpingitis than to appendicitis; probably less so as the organisms of acute salpingitis were usually of a less virulent order.

Mr. Bourne had traced 11 cases of acute suppurative salpingitis operated on within a few days of the first onset of pain. There had been no deaths, and all the cases had done well. From the arguments set forth, that medical treatment was very liable to be followed by chronic disease, and that the risk of early operation was extremely small, the case for early surgical interference appeared to Mr. Bourne to be established. Further, our knowledge of the pathological processes going on within the tube indicated that the earlier surgical treatment is undertaken the better.

The Operation.—Mr. Bourne then described the steps of the operation. The abdomen is opened and the abdominal cavity proper carefully packed off. The tubes are seen to be greatly congested, and plum-coloured, with œdematous fimbriæ and pus leaking from the abdominal ostium. Plastic lymph adheres in flakes to the peritoneal surface of the tubes, intestines, ovaries, and uterus. Organised adhesions have not yet had time to form. Each tube is slit up as far as possible along the border opposite the mesenteric attachment. The pus is very gently swabbed away, and the mucous membrane carefully inspected. Should it appear intact to the naked eye—i.e., only congested without ulceration or greyish patches of necrosis—the tube should be left in situ without any further treatment beyond a few sutures of thin catgut at any point where there is arterial bleeding. Any cyst in the ovaries should be opened freely to prevent the formation of ovarian abscess. A drainage-tube is placed to the bottom of the pouch of Douglas and the abdomen closed. Drainage may be provided through the vagina. If after laying open the tube, the mucous membrane shows patches of ulceration and gangrene it is beyond the power of functional recovery and should be removed. The only possible object of preserving the tubes is to maintain their function, and if this appears impossible, owing to the extent of their destruction, the tubes should be completely removed, as then there can be no further salpingitis, and the ovary is saved considerable risk of infection. To leave the tube alone, and merely drain the pelvis, is to invite the formation of chronic tubal disease and permanent ill-health and the formation of residual abscesses.

Mr. Bourne concluded that in the many cases of acute salpingitis occurring in young women soon after marriage, in whom the certainty of future sterility is a very real tragedy, we were apt to regard the "recovery" of the patient as the chief, if not the only, aim of our treatment. He claimed that our treatment should be designed with a view also to preventing sterility, or at least morbidity. Many of these patients would "recover" in any case. Early salpingostomy would give them the chance of subsequent pregnancy, and if already too much damaged, salgingectomy would prevent permanent ill-health.

Desirability of Early Operation.

The **President** congratulated Mr. Bourne and agreed with him. He recalled old days at the Middlesex Hospital, when these cases were admitted and treated in the medical wards. After months of illness some of these cases developed fistulæ and discharged indefinitely. Some died. Later cases were transferred to the surgical and gynæcological wards for operation. Some of the operations on long-standing cases or cases of large hydrosalpinx were most formidable affairs, owing to the extent and density of the adhesions. Dispassionately reviewing this experience, the President came to the conclusion that this old expectant treatment was all wrong. If it were dangerous to operate early, this discussion would be futile. But it was not so. For 20 years he had been operating as early as possible, and had had good results. It was now well recognised that early operation was not dangerous. The problem remained whether the possibility of functional recovery made it worth taking an additional risk to save the tube. The President had not had a large number of cases in which he had conserved the tube. In two cases he had had to operate again at a later date for chronic disease. He had not, perhaps, done such an extensive slitting of the tube. Early operation with removal of the tube was safe. Evidence now showed that slitting the tube and leaving it was also safe. Even if the "gutter" remained open there was required evidence that the uterine ostium becomes patent. A few years ago he would have said that once a tube was sealed its function was gone for ever. Now, in the face of many plastic operations, he hoped some proof would be forthcoming that this operation might be successful. Pyosalpinx and tubo-ovarian abscesses were a disgrace to modern surgery. The parallel Mr. Bourne had drawn between salpingitis and appendicitis was quite fair. Early operation in salpingitis enabled one to save at any rate the ovary.

Dr. **Carlton Oldfield** said that the important thing was to find a case where early salpingostomy had resulted in a subsequent pregnancy. He had investigated the cases at Leeds and had divided his cases into two groups; the first group was composed of cases where at laparotomy one tube and ovary had been conserved. In some of these cases the one tube appeared normal; in others it was inflamed and oozing pus, but appeared to him capable of recovery. In this series there were 17 cases. Results: no pregnancies. The other group consisted of cases of pelvic peritonitis. In these cases Dr. Oldfield performed posterior colpotomy, and did not open the abdomen. There was pus or serum in the pouch of Douglas. In this series there were 30 cases. Result: one pregnancy. A point in favour of early operation which had not been emphasised was that the salpingitis was frequently unilateral at first, and removal of the diseased tube might save the other.

Dr. **John Campbell** said he had strongly advocated early operation at the discussion at Glasgow last year. The difficulty was to get these cases early. But that difficulty had been largely overcome when applied to the appendix, and it was only necessary to train the profession and the public. As regards the operation itself, a weak point in the slitting up the tube was the necessity for drainage. The drainage-tube must cause adhesions. The operation of colpotomy did not come into this discussion as it was useless for acute cases. Was there any evidence that slitting open the tube predisposed to extra-uterine gestation?

Prof. **R. W. Johnson** did not agree that acute salpingitis was parallel to acute appendicitis. In salpingitis there was an inflammation of the whole genital system, and the disease itself was not dealt with by slitting and draining the tubes. One might as well open Bartholin's gland for acute gonorrhœa. The sterility was probably due to damage done to the whole genital tract by gonorrhœa. There was some danger in early operation. There was not necessarily a large mortality, but there must be some cases where the infection was spread locally, or where general septicæmia developed.

Mr. **Leonard Phillips** read a description of 25 cases of sterility due to sealed tubes resulting from a previous salpingitis. The lesions found varied. In some the abdominal ostium was sealed. Others had definite strictures in the length of the tube, and in others there was a stricture of the uterine ostium. The patients complained of sterility, and many of them had the cervix dilated for this. They gave a history of previous salpingitis, but had no symptoms when seen by Mr. Phillips. The conditions described were seen, as they were all cases on which he had performed abdominal section for plastic operation on the tubes. Of this series there were five cases who had subsequently become pregnant. Mr. Phillips demonstrated by diagrams four different types of operation for the different lesions he had found and described the operations in detail.

Dr. **Gilmore Currier** showed an apparatus for passing gas through the cervix to determine the patency of the tubes. The apparatus consists of a "sparklet" bulb, a steel bulb containing compressed CO_2 and a high pressure valve for controlling the flow of gas, which is led by a tube to a water meter and thence to a hollow uterine sound. Connected to this is an ordinary mercury manometer. The hollow sound is made of pure tin and can be bent into any desired shape. A certain distance from the end is a rubber "acorn" which, by being pressed against the external os, prevents the regurgitation of gas. With the usual surgical precautions the sound is passed and the gas turned on slowly. The pressure rises in the manometer. If the tube is patent the pressure does not rise above about 80 mm. of mercury. There are slight variations in individuals. By the meter it can be observed that gas is passing into the abdominal cavity. This can be confirmed by X ray. If the tube is not patent the pressure gradually rises. It is not advisable to allow the pressure to go above 200 mm.

Mr. **L. C. Rivett** had seen a demonstration of Dr. Currier's apparatus and had observed the difference when the air passed through the tubes or was held up. It would obviously be of great value in the cases recorded by Mr. Phillips, both in diagnosis and in inflating the tubes during laparotomy. As regards Mr. Bourne's paper, Mr. Rivett was in agreement with this method. He was not sure that it was necessary to remove the tubes, even when definitely damaged, as Mr. Phillips's cases proved that it was worth conserving a tube whenever possible; even if resolution was not sufficiently complete to leave it patent, this could be remedied at subsequent operation. The danger of septic secondary hæmorrhage in the delayed operation had not been mentioned. The risk was absent in the early operation.

The **President**, in calling on Mr. Bourne to reply, said that there was not the clear consensus of opinion that he had hoped for. He was disappointed that there was no case recorded where early salpingostomy had resulted in a subsequent pregnancy. Mr. Phillips's results were remarkably good and he could not help thinking Mr. Phillips had been a little lucky. The President was interested in Dr. Currier's apparatus and thought it would be most useful.

Mr. **Bourne** replied.

THURSDAY, JULY 26TH.

Mr. **Comyns Berkeley** opened a discussion on the

Use and Abuse of Forceps.

He drew attention to the unsatisfactory position of the forceps operation to-day. The blame was not all on the family doctor and the teachers of obstetrics must shoulder their share. The General Medical Council could prescribe more stringent rules and regulations. The majority of students were not going to operate when they got into practice, and yet, before they could sit for their final examination, they must spend three months in the out-patient and six months in the in-patient surgical departments of their hospital. The majority of students were going to practise midwifery, and yet many of the examining bodies did not compel them to attend any cases in hospital, and there was no rule that any of the 20 cases should be delivered under the immediate supervision of the chief of the department. The only way to obtain a real knowledge of the bad results of midwifery, and among other things the abuse of forceps, was to attend the practice of the gynæcological ward, and yet this was not compulsory. The whole difficulty in teaching obstetrics was that of obtaining sufficient material. There are far too few lying-in hospitals, and the few obstetric beds in general hospitals are often filled with difficult and abnormal cases. In the medical and surgical wards one patient was available for the study of many students, but in the obstetrical wards one patient was only available for one student. A proper hospital obstetric service was an absolute essential to the efficient teaching of midwifery.

Ante-Natal Treatment.—The true conduct of labour began with ante-natal treatment. Although the forceps on occasions must be and should be used, the less frequently this instrument was employed the better. The proper way to accomplish such a reduction is by efficient ante-natal supervision.

No doctor should agree to attend a woman in labour unless he was prepared to examine her on occasions, more especially in the last few weeks of pregnancy. It was not compulsory for a student to attend the ante-natal department, always supposing there was one. Many men do not mind admitting that they were not always sure whether the head of the child was engaged or not, and yet the head remained the best pelvimeter we had got. The better the doctor was at abdominal palpation, the fewer vaginal examinations he had to make.

The forceps was used most frequently for inefficient pains and disproportion between the head and the pelvis. Proper ante-natal supervision, by getting the patient into as good a state of health as possible, could do much to help the efficiency of the pains. Proper ante-natal examination would lead to the detection of disproportion between the head and the pelvis, of malpresentation, and of those cases of minor contraction in which the head of the child was not engaging as it should—a knowledge of which might easily avoid the abuse of forceps. A man in general practice had very little need to perform surgical operations, but many of the operations in midwifery he had to perform, whether he liked it or not, whilst the public expected him to use forceps as a matter of course, and this without a proper training. In most surgical operations the surgeon made ample arrangements, and was well paid. In the majority of forceps operations arrangements were not made beforehand and the doctor was certainly not well paid.

It was impossible to sterilise the vagina. It was therefore impossible to pass anything into the uterus, be it fingers, hand, or forceps, without potentially infecting it; and moreover from the darkness, warmth, and serum present the uterus rivalled in its ability to encourage the growth of pathogenic organisms any suitably prepared culture-tube in a bacteriological laboratory. If a non-operating practitioner performing a small operation found a big one was necessary he would get expert help. The trouble was that an ordinary pull with the forceps having failed, the doctor did not realise that he was up against something serious. He did not get help, but pulled all the harder. It might be impossible to obtain an anæsthetist, but there was no reason why rubber gloves should not be carried in every midwifery bag, and there was no difficulty in shaving the vulva or in applying an antiseptic. He feared that in the majority of cases rubber gloves were not worn, nor was the vulva shaved. With the ordinary operation the surgeon was not persuaded by the patient or her relations to operate; on the contrary, the strongest objections might be raised by the one or the other. But the doctor attending a confinement was liable to be constantly reminded that Mrs. So-and-So had instruments and labour was terminated quickly and easily. That the forceps was often used unskilfully was due to the fact that, in the past at any rate, a large number of men had not seen them employed before going into practice.

Methods of Using Forceps.—The methods of using the forceps were open to abuse. The instrument could be used as a tractor, compressor, rotator, lever, and stimulator. In Mr. Berkeley's opinion the only warrantable use to which the forceps should be put was that of a tractor. Certainly there were better and safer ways of stimulating uterine contraction. None, except the most ignorant, would in these enlightened days think of using the forceps as a lever. All the cases which he had known, in which such a use had been made of the instrument ended disastrously for the mother, either in fearful laceration or in her death. He knew that many practitioners thought that in cases of persistent occipito-posterior positions, rotation with the forceps is a good method of treatment, and it was often used as a first choice. In nearly every case, especially where the patient had been watched carefully in the early stages of labour, it was possible to rotate the head and shoulders with the hands. The child certainly was more likely to be injured with rotation by the forceps, and he had seen most serious laceration of the mother. To use forceps to make the diameter of the head smaller—that is, as a compression—was absolutely wrong. This instrument must exert a certain amount of compression unfortunately, but this must be avoided as far as possible by allowing its handles to remain loose at frequent intervals. There remained traction, the one proper use to which this instrument could be put. Even this use was frequently abused. The force used should be strictly limited. There existed doctors who stated that they had to pull with all their strength, perhaps with the aid of one foot against the bed. If great force had to be used, it is a sure indication that forceps was not the right treatment. It was an abuse to apply forceps too soon—that is, before the cervix is fully dilated, either by Nature or, in cases of necessity, by hand; or in cases of disproportion, before the head had had time to mould. To apply the forceps in exhaustion of the uterus, or after the death of the child, was to apply too late. It was not fair on the forceps to use it before emptying the bladder with a catheter, neither was it fair on the patient. A vesico-vaginal fistula might easily result in the absence of such precaution, and yet some people were so apt to forget this that they always kept a catheter tied to one blade of the forceps. Lastly, if difficulty was experienced in applying the forceps by one who was accustomed to use this instrument, this was generally an indication against the operation.

Advocates of frequent use of forceps claimed that it shortened the woman's suffering. Was this worth the increased risk? Many asserted that they get less tears, but laceration of the vaginal walls and cervix might not be recognised, and Mackenrodt's ligaments were often badly stretched. It was more difficult to maintain asepsis if forceps was used. Those who were in charge of lying-in and gynæcological beds were constantly having brought to their notice the disastrous results of the unskilful use of forceps—such as rupture of the uterus, rupture of the vagina, fistulæ of the bladder and rectum, whilst fracture of the pelvis was not unknown. During the last year Mr. Berkeley knew of two cases in which the blades of the forceps had been forced through the vaginal walls and applied outside the lower uterine segment.

Indications for Forceps.—A doctor should never use the forceps merely to suit his own convenience; such use, to say the least of it, was unscientific. The rule that if a primigravida had been in the second stage of labour for over two hours, or a multipara for over an hour, she should be delivered was a most pernicious one. If the delay was due to inefficient pains, forceps should be used when they were becoming inefficient; when they had ceased post-partum hæmorrhage was lurking round the corner. If the delay was due to slight disproportion accurate diagnosis was of utmost importance. External measurements of the pelvis mostly indicated the shape, and the diagonal conjugate only showed gross contraction. In medium contraction the practitioner should not interfere unless he is forced to do so. He should be guided by the condition of the mother and child, and if this was satisfactory he should hold his hand. It was far better that the second stage of labour should last six hours than that the mother and child should be injured or killed. If the head was movable above the brim forceps should never be employed. If there was the least doubt about the head being able to pass the brim, forceps should not be used, as this only increased the danger if Cæsarean section was decided upon. Munro Kerr had reported that since the abolition of "high forceps" in the institutions with which he is connected spontaneous delivery had become more common.

Dr. John Fairbairn said that too much reliance had been placed on the forceps. Our first line should be to investigate and treat so that patients should have a normal labour. Ante-natal supervision should eliminate malpresentations and misfits. Once the doctor had satisfied himself that everything is normal the greater part should be left to the midwife, and the doctor, with the rattling bottle of chloroform, should be kept in the background. Hypnotics should be given if required. The fees now paid were too small, and the general practitioner cut the loss by time-saving devices which were equally appreciated by the patient. Mr. Berkeley had suggested that the teachers should supervise the students. Dr. Fairbairn did not agree; he considered that this would be using a steam hammer to crack a nut.

The President (Mr. Victor Bonney) agreed with the views expressed by Mr. Berkeley and Dr. Fairbairn, but they were idealistic. The lot of the general practitioner was hard, and unless he pleased his patients he lost custom; patients and relatives constantly pressed doctors to get on. The President had always advocated that obstetrics should be more surgical. It should be properly paid and properly arranged for. Full dilatation of the cervix was a misunderstood term. It was generally interpreted to mean the cervix sufficiently dilated to allow the head to come through; the term should be altered to "head *through* cervix." In regard to abdominal palpation, it is always a matter of opinion whether a head would come through. Anyone might make a mistake, and when it was found that the head would not come through, the mistake should be admitted and no attempt should be made to use undue force. Sometimes other methods of delivery should be adopted. Perforation was not done often enough when forceps failed after a reasonable chance. The woman should be left fit to bear another child.

Dr. T. A. M. Forde thought that the provision of more beds could only be realised by establishing special lying-in hospitals. Lunacy and fevers were already learnt by the student outside the teaching school and midwifery should be on the same basis. There should be more opportunities for post-graduate work.

Prof. R. J. Johnstone said he agreed that the teaching was poor, but when he had suggested that every student should *see* five obstetric operations before being signed up, it was turned down by the teachers, who said they had not time or cases. Puerperal sepsis often occurred when forceps had *not* been used. This was not a matter for congratulation. The perineum should be more efficiently cleaned up in normal deliveries.

Dr. H. B. McCaskie said that from the general practitioner's point of view these ante-natal precepts were rather disturbing. Practitioners often came home at 4 A.M., congratulating themselves on having saved two lives. Now it appeared they should regret that they did not examine the case a month before. The general practitioner did not see much sepsis after forceps.

Dr. C. E. Douglas gave an excellent description of the life of a country practitioner in Scotland.

Colonel A. Buchanan showed some models which he was demonstrating in the afternoon, and pointed out how they indicated when to use forceps.

Many other speakers, including Mr. R. A. Hendry, Dr. J. Campbell, and Mr. L. C. Rivett took part in a very interesting and full discussion, and Mr. Berkeley replied.

SECTION OF RADIOLOGY AND ELECTROLOGY.

Wednesday, July 25th.

Dr. Gilbert Scott (London), President, introduced Dr. R. W. A. Salmond (London), who read a paper on the

X Ray Examination of the Urinary Tract.

Dr. Salmond in his opening remarks said that the success of X ray examination of the urinary tract depended upon two main factors: (*a*) proper technique, and (*b*) accurate interpretation. Under the head of technique the speaker directed attention to the undermentioned points: (1) The apparatus used should be capable of making the correct exposure in a fraction of a second, or in two or three seconds at the most. It was possible to do good work with longer exposures provided the kidneys were kept at rest by efficient compression. In any case compression should be used. (2) Preparation of the patient should consist in a regimen of light diet for two or three days, with an aperient on the two evenings preceding the examination, followed by an enema on the day of the examination. (3) The tube should have just sufficient penetration to get through the parts. (4) The film should include the last two ribs and iliac crests and the back should be in close apposition to the film. (5) The central ray should be directed through the level of the second lumbar vertebra with the extension tube pointing under the costal cartilages. (6) In all cases the whole urinary tract on both sides should be examined. (7) In the examination of the ureters the tube should be parallel with the film. (8) In examining the bladder the tube must be tilted in such a way that the extension tube points well into the opening of the pelvis so that the pelvic bones do not hide any shadow at the base of the bladder. (9) The Potter-Bucky diaphragm gives excellent results in these cases.

Under the head of accurate interpretation Dr. Salmond said that in all cases where a doubtful shadow is found confirmatory films should be taken on another day after further purgation. Lateral views of the kidneys could be taken to show better the relation of the shadows to the kidney or ureter and were especially useful in differential diagnosis. In stout people the outlines of the kidneys were best shown by inflating the perirenal fat with 200–600 c.cm. of oxygen or CO_2. The kidney could also be shown by inflating the peritoneum and this method was good for showing renal tumours, though not free from danger. The most simple and the safest method was to pump air into the colon, a method which was also painless. Pyelography consists of injecting an opaque solution into the pelvis of the kidney through a ureteral catheter. 10–20 per cent. solution of sodium iodide or bromide is generally used. Collargol should be avoided, being too irritating. Pneumo-pyelography is a similar method except that oxygen is used instead of the solution. It does not obscure stones as does the opaque solution. To demonstrate the bladder it should be filled with a 10 per cent. solution of sodium iodide or an emulsion of barium and oil. Diverticula and calculi can be seen, but films should be taken at different angles.

As regards diagnosis, the normal size of the kidney must be clearly visualised. Marked difference of the two sides was pathological. Kidney stones were shown superimposed on the kidney shadow and always had the same relation to it on movements of respiration. However, the pelvis and calyces were usually characteristic. Viewed laterally they were seen superimposed over the bodies of the first to the third lumbar vertebræ. Shadows in the kidney area might be due to intestinal contents, calcified glands, calcification in a tuberculous or malignant kidney, or to foreign bodies. Calcified glands generally presented a mottled appearance and had extreme mobility; the lateral view showed them in front of the vertebræ. Gall-stones usually showed a clear central nucleus and denser peripheral area, and these moved vertically on respiration. Multiple stones were characteristic. Stones in the ureter were usually small and oval. They might travel up and down the ureter. Calcified abdominal glands, accessory epiphysis for the tip of the transverse process, concretion in the appendix, phleboliths, might all be mistaken for ureteral calculi. When a diagnosis could not be made it might be necessary to pass an opaque bougie up the ureter. Vesical calculi were usually larger than renal ones and were generally oval in shape. Often they showed different densities due to the deposit of layers of different chemical compositions. Diverticula were demonstrated by filling the bladder with an opaque solution and taking films at different angles. After the fluid was voided the diverticulum might remain filled. The differential diagnosis of vesical calculi was to be made from prostatic calculi, fæcal masses, calcified fibroid, dermoid cyst, and foreign bodies. In the detection of urethral stones the tube must be well tilted to avoid the pubic arch. For these the commonest site was the prostatic urethra, but stones might be found in any part of the urethra and might be formed by phosphatic deposit behind a stricture. Uric acid stones would not cast a shadow, and radiologists should mention this in reports on negative cases. All other stones threw a definite shadow. Calcium oxalate cast the densest shadows, then phosphatic deposits, and lastly those composed of urates. Cystin and xanthin stones gave a shadow due to the contained sulphur element. Stones were frequently found in infants and children and might produce no symptoms for years. With the proper technique and assistance of the more elaborate methods and with accurate diagnosis in collaboration with a urologist there is no doubt that the value of X rays in urinary diagnosis, especially as regards the presence or absence of a stone, is of the very highest importance.

Mr. R. OGIER WARD (London) pointed out that, contrary to the usually accepted opinion, pyelography was neither difficult, dangerous, nor painful; though it might be tiresome perhaps to the radiologist and the patient. He did not approve of the administration of an anæsthetic, the sensation of the patient being an important guide. The solution recommended was 20 per cent. sodium bromide injected at body temperature. Mr. Ward said the chief use of pyelography was in the determination of the condition of the kidney. He also mentioned that X rays were of value in ascertaining the presence of prostatic calculi.

Dr. L. A. ROWDEN (Leeds) advocated the merits of screen examination with palpation, and pointed out the following advantages of this method: (1) correct quality of rays for the particular case in hand can be obtained; (2) the kidney triangle can be accurately illuminated; (3) the movement and position of any shadow or shadows can be noted; and (4) the shape, size, and density of any shadow can be observed and also whether the object causing it is nearer to the anterior or posterior abdominal wall. He referred to a paper published by him in 1910 on the value of screen examination in the diagnosis of renal calculus and said that since that time they had found it of the utmost value. Dr. Rowden prepares his patient for three days, giving a light diet and a vegetable aperient sufficient to cause two or three loose motions a day. He deprecated the use of enemata as having a tendency to form gas in the colon. He pointed out that the skin of the lumbar region should be examined for pigmented moles, as these may cause a slight shadow. The patient should be placed on the X ray couch face downwards, with a cylindrical air cushion under the abdomen just below the costal margin. The X ray tube is placed under the couch in a large lead-lined box which is free to move in any direction on wheels. The diaphragm should be fixed, small and tubular, and by running the tube-box up and down the couch and from side to side the whole of the kidney area can be quickly examined. A calculus which can be quite distinctly seen through a very small diaphragmatic opening rapidly disappears when the opening is enlarged. Certain fallacies may occur with this method, and Dr. Rowden pointed these out and indicated how they might be avoided. He said that shadows not caused by calculus within the renal triangle may be due to: (1) calcareous mesenteric glands; (2) calcareous retroperitoneal glands; (3) foreign bodies, as pills, scybala; (4) calcareous deposits in lower costal cartilages in old people; (5) phleboliths; (6) calcareous deposits in a tuberculous kidney; (7) pigmented moles on the back; (8) mottling of the renal area due to gas in the intestines; and (9) gall-stones.

Dr. G. B. BATTEN (London) gave details of an interesting case of renal calculus with several stones on one side and a large one on the other.

Dr. JAMES METCALFE (London) emphasised the importance of correct technique and insisted that the film was more accurate than any visual observation could possibly be. Dr. Metcalfe also referred to the work of Dr. Carelli, of Buenos Aires, in perinephritic injection of oxygen and carbon dioxide. Dr. Metcalfe bore testimony to the use of the Potter-Bucky diaphragm in renal radiography, especially in fat people.

Dr. R. MAITLAND BEATH (Belfast) showed diagrams of, and drew attention to one of the conditions in which pyelography was of great value. This condition consisted of a kinking of the ureter with an abnormal renal artery bending round it and compressing it. Without pyelography it is doubtful if this condition would have been recognised, but having been diagnosed by this means the artery was divided and the condition relieved.

The PRESIDENT, in summing up, dealt with the subjects and with the questions that had been raised in an extremely practical manner. His chief points were as follows: (1) Preparation of the patient—i.e., castor oil the night before, and light diet. (2) Efficient compressor and efficient compression. He used a sugar-loaf cushion filled with picked lamb's wool. This was passed just under the costal margin and pressure applied. (3) The tube above the patient. (4) Length of exposure. In connexion with this he said that lightning rapidity was not essential. (5) The extreme value of showing the renal outline. (6) Perirenal inflation, which he said was not done often enough. (7) Team work between the surgeon and the radiologist should be encouraged.

Dr. SALMOND replied briefly, and said that in his experience he had found that gall-stones were not homogeneous as quoted by Dr. Rowden, but that they were less dense at the centre.

THURSDAY, JULY 26TH.

Dr. GILBERT SCOTT (London) surrendered the chair to Dr. W. J. TURRELL (Oxford), who thereafter presided until the close of the meeting. Dr. Turrell announced three papers on

Medical Diathermy.

Dr. E. P. CUMBERBATCH (London) said that medical diathermy could produce therapeutic results that no other form of treatment could effect. At present there was a pressing need of larger and more powerful machines; with electrodes measuring 8 in. by 4 in. the current density was low, even if the machine were used "all out"; larger electrodes than these were required for abdominal work, but with the present machines there would be very little heating effect. Air spark-gaps with mica washers became too hot with prolonged use and the current was cut down. Gaps working in an atmosphere of gas, and which could be regulated while working, were preferable, but in these there was an accumulation of soot, so that they required cleaning after about ten hours' use. It would be an advantage if the metal surfaces of the gap could be replaced when worn, as they corroded and became uneven after much use. In treating the abdomen the current had little resistance to overcome, so that the amount of heat generated was small, and it was quickly conducted away owing to the abundant blood-supply of the organs. When a thermometer was placed in a deep sinus in the kidney region following a nephrectomy no rise in temperature was recorded, although the current was passed for 20 minutes at 1·2 ampères, the electrodes measuring 8 in. by 4 in. Fürstenburg and Schemel measured the heat generated in the stomach with a special instrument. Using 12 in. by 8 in. electrodes and a current of 0·3 ampères the maximum rise was 0·4° C., and with 2 ampères a rise of only 0·1° C. was obtained. It was possible that strong heating of the skin sensory nerve-endings caused a reflex stimulation of the deep circulation, so that the heat was more rapidly conducted away. It must not be assumed, therefore, that maximum current and maximum heat produced the best results. In the case of mucous membranes the low resistance required a stronger current to produce the same degree of heat.

Good results had been obtained in the treatment of gonococcal infection of the joints and other parts. Nagelschmidt claimed excellent results in treating angina pectoris; and præcordial pain in arterio-sclerosis had been relieved by the application of diathermy to the heart region. Bordier spoke highly of its use in the treatment of cold paralysed limbs in anterior poliomyelitis. It was most valuable in the treatment of pains and spasms accompanying hæmorrhoids when applied by means of a rectal electrode.

Diathermy was an efficient means of treating dysmenorrhœa by relieving the congestion and spasmodic contraction. Bordier treated one case by placing one electrode in contact with the cervix, the other being on the hypogastrium. It should also be tried in para- and peri-metritis.

Diathermy had been tried by workers in the U.S.A. and in Germany for pulmonary tuberculosis, and it had been said that the symptoms were greatly relieved. If it possessed any therapeutic action it must be due to the increased blood and lymph flow and not to any germicidal action, as the temperature employed was not sufficient to kill the bacilli. Hypothermia, local and general, neuritis, and high blood pressure are all amenable to this treatment.

Dr. C. A. **Robinson** (London) amplified the remarks of Dr. Cumberbatch on the use of diathermy in the treatment of gonorrhœal rheumatism. He had treated some 120 cases, 18 of which were confirmed bacteriologically, and he was convinced of the utility of the current in this disease. It was necessary to treat not only the joint, but also the focus of infection; in fact, it was in all probability this latter which was the more important. He deduced this from his observations in cases of gonorrhœal arthritis in the female, in which the cervix only had been treated. Dr. Robinson, in these cases, gave three to five treatments bi-weekly, from 500 to 1000 milliampères, the uncovered portion of the sound measuring ¾ in. if for the cervix, and 1½ in. if for the urethra. In the male the application was made to the prostate, and sometimes to the urethra, though this latter method had not been so satisfactory. Dr. Robinson used the pure tin electrode for the cervix; in cases of gonorrhœal epididymitis he used a soft lead electrode. Satisfactory results had followed all these applications.

Dr. F. Howard **Humphris** (London) read a paper enlarging upon the use of medical diathermy in the reduction of high blood pressure, in pneumonia, and in tuberculosis, both of chest and joints. In hyperpiesia—that is, in the pre-sclerotic state, which might exist without any sign or symptom—medical diathermy administered on an auto-condensation couch might check the process of degeneration and prevent arterio-sclerosis taking place. Dr. Humphris gave a group of symptoms, chiefly functional, which might indicate a commencement of arterial change. There might be, he said, attacks of transient giddiness, a heavy oppressive fullness in the head, headache often intensified with effort of mental concentration ("the sign of painful thought"), or the headache might be pulsatile in character; there might be insomnia or drowsiness, especially in the morning, with a disinclination to work and an inability to concentrate the attention, alternating perhaps with an irritability of temper and occasionally with a mild psychic exaltation with a confusion of ideas; failure of memory, noises in the ears, migraine or neuralgia, general nervousness with anxiety, or a sense of impending evil impossible to define.

The way in which the current acted in lowering blood pressure could be said to be twofold. One, the general or constitutional effect as affecting metabolism, and the other, the local effect as on the vasomotor system. These had been demonstrated both chemically and clinically. He pointed out that even when arterio-sclerosis was established, by the use of this current a patient could be kept in a condition of safety. Dr. Humprhis urged the use of diathermy in cases of pneumonia. The treatment, he said, was a rational one and one not difficult of application. The electrodes measured about 5 in. by 3 in., and one was placed on the back and one on the front of the congested area. With the heat applied directly through the pneumonic patch a dilatation of the vessels, and consequently a decongestion, took place. The increase in temperature was beneficial, probably because it exercised a deleterious effect upon the bacilli causing the disease. A few treatments appeared to cause a rapid amelioration of the symptoms. Notably the breathing became easier and the cyanosis lessened, indicating that increased air absorption by the lungs was taking place and the heart was better able to perform its functions, owing to the diminished resistance in the pulmonary circulation.

He wished to associate himself with Dr. Cumberbatch in his remarks on pulmonary tuberculosis, and indeed in tuberculosis of bone as well, and this again, he thought, was due to the fact that the current caused a rise in temperature in the tissue through which it passed. Certainly the local increase in temperature, with the resultant improvement in the circulation and lymph flow, favoured phagocytosis, metabolism was more active, toxins were eliminated, and with the diminished fighting power of the bacillus and the increased resistant power of the body the current assisted a return to normal in the tuberculous areas. The method of treatment of tuberculosis is deserving of fair trial, and it would certainly seem to offer symptomatic relief and possibly a radical cure. Other countries, as Dr. Cumberbatch said, were trying it, but in so important and urgent a matter as the treatment of tuberculosis by electricity why should other countries lead?

Dr. **Turrell** said that the secret of success in medical diathermy consisted in administering currents of moderate intensity for long periods, such as 40 minutes or an hour, and not in giving intensive treatments of short duration. He said that the object in administering medical diathermy was not merely in order to heat the tissues by the conversion of electrical energy into heat energy within the body, but in order to obtain the consecutive effects of this heat, namely, the relaxation of spasm, the increased tissue drainage, the increased nutritional effects, &c., which were brought about by the increased blood-supply resulting from the generation of heat within the tissues in the body. There was a mass of experimental evidence that the abdominal organs were heated by diathermy in the same manner as any other organs of the body, though not perhaps to the same extent, for owing to their more free blood-supply there were larger numbers of hydrogen- and hydroxyl-ions present. Their conductivity was therefore higher and their resistance lower, consequently they retained heat less than the other organs. Moreover, not only were the abdominal organs very efficiently " blood cooled " in this way, but they were very directly affected by the heat regulating mechanism of the body, as was well shown by the experiment of Fürstenburg and Schemel quoted by Dr. Cumberbatch. Teleman, as early as 1911, experimentally heated nearly all the organs of the body in animals by diathermy. The experiments of Berndt and Preyss on animals afforded further proof of the heating effects of the diathermy currents on the abdominal organs. These two workers pointed out the danger of overheating the intestines by diathermy when they were distended with gas. In such cases they found that there was a danger of a great intensity of current on the inner coating of the intestine, and that this caused in some of their experiments a necrosis of the intestinal folds.

The time had arrived, Dr. Turrell said, when we should discuss diathermy not in relation to its action in isolated cases and diseases, but rather in relation to its mode of action. In this way we should better realise what a very wide range of application it possessed. We should not turn to an index of electrical treatment and look up Neuritis—diathermy; Chilblains—paraffin wax bath; Acne—ultra-violet radiation, but we should ask ourselves, would this case of spasmodic dysmenorrhœa be relieved by the relaxation of spasm consecutive on diathermy? Would this unresolved pneumonic lung be improved by an increased arterial blood-supply and accelerated tissue drainage, and could these results be secured by diathermy? That, he submitted, was the scientific method; and if we adopted it we should soon recognise in what a large number of cases the consecutive effects of diathermy are beneficial. Dr. Turrell said that in cases of arthritis of the hip he is in the habit of using electrodes 20 by 10 cm. with 2 ampères for 40 minutes once a week for a year, this having a prelude of daily treatments for a short time, then treatments three times a week, then twice a week before commencing the weekly régime. In dysmenorrhœa and coccydynia he had found diathermy very useful. Pain in hæmorrhoids he had seen relieved even after it had existed for four years. In fact, he foresaw the time when no ward in a hospital, either medical or surgical, would be complete unless there were a diathermy apparatus installed therein.

Dr. **Batten** pointed out how the diathermy currents had a definitely deleterious effect on the growth of the bacilli. He had had good results in the application of diathermy to the tonsils in cases where tonsillectomy was contra-indicated. He endorsed the opinions of the previous speakers on the value of this current in hæmorrhoids, and said that, speaking from an experience of 25 years, he knew of cases that had remained well for four or five years, with absence of pain.

Colonel C. B. **Heald** (London) agreed with all that Dr. Robinson had said in regard to gonorrhœal arthritis. He had also had uniform success in the treatment of cold limbs occurring in the different forms of paralysis, especially anterior poliomyelitis, and he instanced one case which was of 14 years' standing. Colonel Heald emphasised the need of educating colleagues who knew much medicine but needed enlightenment in electrical matters.

Prof. S. **Russ** (London), in discussion, remarked upon the desirability of extending the observations with diathermic currents of still higher frequency than were at present used. He also thought that it would be useful to refer to the current passing through the tissues in terms of the current density, which was a rather more exact specification. It was worth noticing that even with the same current density the rise in temperature in the tissues would be greater with large electrodes than with small, owing to the smaller proportionate heat dissipation. In cases where the rise in temperature was very small it would still be of interest to know whether any physiological effects were observed, and if so the question would arise as to whether these effects were in any way due to the oscillatory magnetic field. The effects of magnetic fields of lower frequency had been studied to some extent, practically the only substantiated physiological effect being that upon the eye.

Dr. **Agnes Savill** (London) stated that she had some experience with the treatment by diathermy of gonorrhœa in women, combined with ionisation, and recently had two cases that had responded well to this method, when curettage and treatment in skilled hands by the more established methods had failed. Dr. Savill used a copper electrode and 1 ampère for 10 to 12 minutes, which was followed by immediate improvement. Her results were checked by bacteriological examination.

Dr. **Florence Stoney** (Bournemouth) reported good results with diathermy in Raynaud's disease, chilblains, and in the reduction of high blood pressure.

Mr. **David Lees** (Edinburgh) had had experience in the treatment of gonorrhœa in women and gonorrhœal infection of the prostate, and in a case of acute prostatitis thought that it should be tried, and he would expect at least symptomatic relief. Mr. Lees thought that it would also seem to be a reasonable remedy for ophthalmia neonatorum, and asked if it had ever been used.

Dr. **Robinson**, in reply, said that he would certainly like to see it used in gonorrhœal ophthalmia. It would be eminently easy to apply, and it afforded a rational means of cure. He would also like to see it employed in cases of malignant endocarditis. Many of these cases were due to the gonococcus, and as nothing else was of much avail he thought diathermy should be tried.

SECTION OF VENEREAL DISEASES.

Friday, July 27th.

With Sir **Archdall Reid**, President of the section, in the chair, a discussion was opened by Mr. **Kenneth Walker** (London) and Dr. **David Watson** (Glasgow) on the

Prevention and Treatment of Chronic Gonorrhœal Prostatitis and Vesiculitis.

Mr. **Kenneth Walker**, who dealt mainly with chronic prostatitis, drew attention to the importance of the prostate as a gateway by which organisms entered both the blood and the lymphatic stream. As a rule, prostatitis and vesiculitis were associated conditions, and considerable confusion in diagnosis between them frequently occurred owing to the fact that the vesicles lay along the upper edge of the prostate in a horizontal position, and to the examining finger induration of the vesicles was, as a result, mistaken for induration of the prostate. However, as the treatment of the two conditions was in the main the same, errors in diagnosis were not of great importance. Of all the therapeutic measures available in the treatment of chronic prostatitis, prostatic massage was the most important. In his opinion the emptying of the follicles brought about by massage was achieved *indirectly* through the contraction of the muscular coats of the prostate rather than by *direct* pressure from the massaging finger. In order to see whether electrical stimulation of the prostatic muscle would prove as efficient as digital massage, he had been experimenting in the venereal department of St. Bartholomew's with a slowly interrupted faradic current applied to the prostate by an electrode in the rectum. Good results had also been obtained with a similar electrode and diathermy, but it was too early yet to say whether electric stimulation of the prostate was as efficacious as digital massage. Another method of treatment that was extensively used was dilatation of the posterior urethra by the passage of large-sized bougies or of special dilators. The bougie probably acted in a similar manner to massage in stimulating the prostate to contract. A Kollman's dilator should, in the speaker's opinion, never be used in the posterior urethra, as it was anatomically impossible to achieve a uniform dilatation of such a complicated cavity as that of the posterior urethra. Already a reaction was taking place against what he would term the great metallic age in the history of the treatment of gonorrhœa. Chronic gonorrhœa was a deep-seated infection, and increasing the variety of urethroscopes, dilators, electrodes, and flushing bougies that were available to the urologist would not lead to final victory. This would be achieved through the biochemist and the bacteriologist rather than with the help of the instrument maker. Although the vast majority of cases of chronic prostatitis finally yielded to patient and prolonged treatment, in a few cases the speaker had been forced to fall back on incision of the prostate and drainage of a small chronic abscess cavity.

Dr. **David Watson**, in introducing the subject of chronic vesiculitis, emphasised the importance of prevention of the extension of infection to the posterior urethra. He employed posterior irrigation as a routine treatment in all cases of anterior urethritis, and considered that its use diminished the risk of posterior infections. The second most important preventive measures were rest during the early stages of the disease and the avoidance of trauma to the posterior urethra. Although Mr. Kenneth Walker had pointed out that the spread of infection might occur via the lymphatics, it was practically certain that the great majority of cases of epididymitis resulted from a reversed wave of peristalsis passing down the vas. For this reason he employed atropine as a sedative and as a prophylactic to prevent extension to the other vesicle or the other epididymis. Vesiculitis, in spite of what American surgeons stated, was a rare disease, and he could not understand why American literature should lay so much emphasis on such surgical proceedings as vesiculectomy and vesiculotomy. In his opinion, these operations were very rarely required, although possibly vasotomy or the injection of the vesicles by the vas might occasionally be required.

Mr. **David Lees** (Edinburgh) stated that though in the main he agreed with what the previous speakers had said, there were certain points on which he must differ. He did not advise posterior irrigation as a routine measure in cases of anterior urethritis. In the majority of cases of early anterior urethritis treatment was carried out by the patient himself or by a more or less skilled orderly, and the risk of trauma to the urethra was too great to make posterior irrigation a safe proceeding. Of the fluids that might be used for irrigation, in addition to those more commonly employed, mercurochrome and nizin had been found to be useful. Like Dr. Watson, he used atropine as a prophylactic measure in the acute stage of the disease, giving it in doses of 1/75th of a grain in a suppository. He had also found sulfarsenol of use in the acute period, but not in the chronic. He agreed with Mr. Kenneth Walker that the action of prostatic massage was probably indirect through the contraction of the prostatic muscle. It was of interest to find Mr. Kenneth Walker in one paragraph advocating the use of a new and rather alarming rectal electrode, and in the next damning the great metallic age in the treatment of gonorrhœa. However, he agreed with him that bacteriological measures, combined with chemical, held out a greater hope of finality in treatment and in permanence of cure.

Dr. **A. E. Cambell** (Portsmouth) dwelt on the importance of early treatment in preventing the development of such serious complications as prostatitis and vesiculitis. Personally he observed the following rules when treating cases of acute gonorrhœa: (1) Never to force irrigation on an unwilling or nervous patient. (2) Never to attempt posterior irrigation during the first week or in the acute stage of the attack. (3) Never to massage the prostate or vesicles for diagnostic purposes until the urine was clear. (4) Never to pass any instrument into the bladder in a fresh uncomplicated case of gonorrhœa. He divided cases of chronic prostatitis and vesiculitis into two categories—cases in which there were no signs or symptoms beyond the existence of pus in the expressed secretions, and cases accompanied by urinary symptoms or by metastatic lesions, such as chronic rheumatism or iritis. In the former class of case vaccines produced little effect, but in the latter they were often of benefit. In addition to the methods of treatment already discussed, he had found the application of heat by a water-heated apparatus in the rectum of use.

Surgeon-Commander **R. J. G. Parnell** agreed with Mr. Lees that detoxicated vaccines were of most value in the acute early stages of the disease. Less than 5 per cent. of cases at Haslar suffered from vesiculitis, and, in his opinion, prostatitis was much more often the primary lesion in cases of metastatic gonorrhœa. Massage was the great stand-by in treatment. From sulfarsenol he had obtained no results, although he considered that the use of ichthyol internally was of value.

Dr. **James Hudson** (Newcastle-on-Tyne) spoke of the abuse of potassium permanganate in the treatment of chronic gonorrhœa. He had seen several cases in which the urethra had been damaged by too strong solutions. Sodium salicylate given by the mouth was useful as a preventive measure.

Dr. **G. L. Eastes** (London) said that vaccine therapy had received some hard knocks from previous speakers, but that a vaccine to be effective must be complete, and must comprise all the secondary organisms as well as the patient's own strain of gonococcus. In acute urethritis vaccines were, in his experience, of the very greatest use in effecting a cure without complications.

SECTION OF ANÆSTHETICS.

Thursday, July 26th.

At the opening meeting of the section, Dr. **William Joseph Essery**, the President, welcomed the presence of colleagues from other districts, and hoped that the stimulating and thoughtful papers about to be read by the distinguished anæsthetists who had written them would be followed by fruitful discussion.

Dr. **Harold Sington** (London) read a paper on

Anæsthesia for Children.

The author divided his subject into four parts: (*a*) the consideration of the preparation of the patient; (*b*) the choice of the anæsthetic to be used; (*c*) a few points on the administration of the anæsthetic of choice; and (*d*) some suggestions for making the recovery as free from discomfort as possible. Under the first head he stressed the importance of refraining from drastic purgation, and the necessity for examining the patient's urine for acetone, which was often the result of sudden change from a very rich carbohydrate to a more mixed hospital diet. Operation must be postponed until the acetone had disappeared. In all cases glucose should be given before operation, as well as a preliminary injection of atropine. In a child of 2 years and upwards as much as 1/100 gr. could be safely given. On the other hand, morphine should be avoided in the case of children. As regards the second heading, ether was the anæsthetic of choice, except when the actual cautery was to be used, and in certain special operations such as dental extractions, where ethyl chloride was preferable. Gas and oxygen was the best anæsthetic in cases of congenital hypertrophic stenosis of the pylorus and of intussusception. Under the heading of the administration of the anæsthetic the author insisted that the anæsthetic of choice should be administered gently and persuasively. A few drops of essence of orange were sprinkled on gauze, and when the child had got used to the smell, ether was slowly dropped on until unconsciousness supervened, after which it could be pushed. The airway should be kept as clear as possible. Recovery could be made much less unpleasant if (1) a drop of ol. ricini were instilled into each eye after the cessation of anæsthesia, (2) the mouth were sponged out with normal saline solution, (3) a rectal sedative were administered, such as, in the case of a child of 10 years, potassium bromide 20 gr., aspirin 10 gr., dissolved in half a pint of normal saline solution.

Dr. A. L. FLEMMING (Bristol) read a paper on

Fatalities from Anæsthetics,

in which he elected to deal with his subject entirely from the clinical standpoint. For some years past the number of fatalities due to anæsthetics had remained practically stationary, despite an enormous increase in the number and severity of the operations performed. Patients were now expected to bear a surgical burden so heavy that without improved anæsthesia the mortality would undoubtedly have been much heavier than was the case. Deaths from anæsthetics might be classified according to what time they occurred during the administration—before, during, or after, operation. In the first group were fatalities caused by the anæsthetic without the intervention of other factors, such as shock, and a large proportion of these were associated with chloroform induction. Chloroform was too dangerous a drug for routine work. The second group was difficult to analyse, but coöperation between the surgeon and the anæsthetist was necessary to avoid overtaxing the patient. When a moribund patient died during operation it was misleading to attribute the death to the anæsthetic. In the third group it was almost impossible to fix the blame. Even post-anæsthetic pneumonia might be the result of tight bandaging and not of the anæsthetic. The surgeon might then call for a change of technique which, while reducing one risk, might induce another. Again, chloroform might be the safer anæsthetic to give to a bronchitic patient, even though there were greater risk during administration. The author brought his paper to a close by discussing some of the difficulties which seem to offer most hope of solution.

Dr. H. E. G. BOYLE (London) read a paper on

Anæsthesia by the Gas-oxygen-ethanesal and the Gas-oxygen-chloroform-ethanesal Combinations,

in which he pointed out that in these methods of anæsthesia attention must be paid to preliminary medication. To children under 14 atropine gr. 1/200 was given, and to those over that age morphine gr. 1/6 and atropine gr. 1/150. For adults of ordinary physique, Burroughs and Wellcome "hyoscine compound A" was ordered, while big strong men received the same firm's "hyoscine compound B." On the whole these preliminary injections gave the best results. The contents of the ether bottle had also to be varied with the patient and with the operation. For children no chloroform was necessary, but young adults and older people did best with a mixture of ethanesal and chloroform in equal parts. For diathermy or the cautery chloroform alone should be used. Nitrous oxide and oxygen being non-toxic, the use of these drugs reduced the amount of the toxic drugs used to a minimum, which was of obvious benefit to the patient. Induction was carried out by the gas and oxygen alone, and this was followed by the introduction of the gases into the ether bottle, so that the gases picked up the vapour of the toxic drugs and passed them on to the patient. When full anæsthesia had been secured the operation was commenced. As soon as the preliminary incision had been made the anæsthetic was continued by gas and oxygen only. The anæsthetist should keep a careful watch for all changes in colour, respiration, &c., and deal with each change appropriately as it occurred, giving more or less oxygen or more or less of the contents of the ether bottle as required. The airway must, of course, be kept free if necessary by an artificial airway. The author brought his paper to a close by referring to the method in the case of throat surgery and its application in operations where endotracheal anæsthesia was necessary.

Dr. CHRISTOPHER MAYHEW (Southsea) demonstrated his apparatus for the administration of warmed ether vapour, the chief advantages for which, he claimed, were its lightness and portability, the complete apparatus weighing only 1 lb., and the whole of it being carried inside its own warming cylinder.

Reviews and Notices of Books.

SURGICAL TREATMENT OF THE TONSILS.

The Tonsils—Faucial, Lingual, and Pharyngeal. With Some Account of the Posterior and Lateral Pharyngeal Nodules. Second edition. By HARRY A. BARNES, M.D., Instructor in Laryngology, Harvard Medical School. London: Henry Kimpton. 1923. Pp. 217. 25*s.*

Tonsillectomy by Means of the Alveolar Eminence of the Mandible and a Guillotine, with a Review of the Collateral Issues. By GREENFIELD SLUDER, M.D., Director of the Department of Rhinology, Laryngology, and Otology, Washington University School of Medicine. Same publishers. 1923. Pp. 176. 25*s.*

IT must be admitted that for many years the surgical treatment of the tonsils was conducted on unscientific lines, and that their surgical anatomy and pathology were inadequately studied and taught. Surgeons were content to treat recurrent tonsillitis by slicing off the prominent part of the gland with a sharp guillotine, and it was not until some 15 years ago that they began generally to realise that this operation was often insufficient and, indeed, frequently did more harm than good by causing stenosis of the crypts and favouring the retention of septic material. To ensure a complete removal of the tonsil with its capsule various methods of dissection were introduced, and, in 1910, Whillis and Pybus, of Newcastle-on-Tyne, and Sluder, of St. Louis, U.S.A., published methods of complete removal by means of a blunt guillotine introduced in a position opposite to that in which it had previously been used, that is, with the handle now directed towards the opposite side of the mouth. The two methods are not identical, for Sluder makes use of the "alveolar eminence" of the lower jaw to dislocate the tonsil through the fenestra of the instrument, while Whillis and Pybus employ the finger for the same purpose. The question of priority is, therefore, of small importance, but Dr. Sluder explains in his book on tonsillectomy that he presented his technique before the American Medical Association on June 9th, 1910, but that publication was delayed until March 25th, 1911; in the meanwhile Whillis and Pybus published their method in THE LANCET on Sept. 17th, 1910.

Dr. Sluder's book is written primarily to describe his method of tonsillectomy, and this he does in a most clear and thorough manner. He claims "perfect results"—i.e., complete removal—in 99·6 per cent. of cases; presumably he uses his method in all cases, but we think that in the hands of the average expert complete removal with the guillotine is less certain in some cases of adult tonsils adherent after quinsy and particularly in cases of tonsils which have been previously cut by tonsillotomy. This is by far the most valuable part of the book, and it has been expanded by a chapter on anatomy and embryology, and on the indications for tonsillectomy, and by a useful chapter by Dr. Arthur W. Proetz on physiology and general pathology. There is a final chapter on removal of adenoids by direct vision, by Dr. I. D. Kelley, the inventor of the method, which, though of interest, is somewhat out of place in this work.

Dr. Barnes's book on the tonsils is on similar lines, but of a more general scope. He describes at length the development, anatomy, function, and pathology of the tonsils, and the methods of tonsillectomy at present most in use, especially dissection and snare, and the Sluder method. Dr. Barnes himself does all his operations by the dissection method for the somewhat inadequate reason that a certain number of tonsils must be removed by dissection, and that he prefers to use only one technique. There is a good chapter on the sequelæ of operation, and the methods of dealing with hæmorrhage are well described, though Coakley's slip-knot ligature is not mentioned; and there is a final article on X ray and radium treatment of tonsillar hypertrophy, of which method his personal experience is disappointing. The short chapter on neoplasms of the tonsil is inadequate. Both books are well produced and beautifully illustrated and should be valuable to the specialist.

Les Cercles Vicieux en Pathologie.

By J. B. Hurry. Translated from the third English edition, revised and enlarged by C. Flandin and F. Françon. Paris: Maloine and Sons. 1923. Pp. 354. Fr.20.

Dr. Hurry's well-known book on vicious circles in disease was first published in 1911 and the third edition was noticed not long ago in our columns. Its translation into French constitutes in reality a fourth edition, for the author has revised and amplified it for the purpose. It is right that such a suggestive piece of work should be so well received. The outstanding point on which the whole theme rests is that diseases are processes and not states—an axiom so elementary that it cannot be emphasised too often. And if the author's particular treatment of these processes lays more stress on the development of secondary disorders than on the attainment of compensations—if he seems to think of disease more as a thing which tends to go from bad to worse than as a series of which restoration and repair is one of the earliest items—it is only to indicate that nature or art may always break the circle and that art is more likely to do it if the existence of the circle is recognised.

Problems in Tuberculosis.

By Sir James Kingston Fowler, K.C.V.O., C.M.G., M.D., D.Sc. (Hon.), F.R.C.P., Consulting Physician and Emeritus Lecturer on Medicine, the Middlesex Hospital. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 64. 5*s.*

Not infrequently the value of books is inversely proportional to their size. This book is small and also valuable. But its value lies not so much in the opinions it voices—some of them will not be widely accepted—as in the expression it gives to a general feeling that all is not well with the tuberculosis campaign in this country. A correspondent, writing to the author, pointed out that leaders do not appear to lead, that many workers have become discouraged and have withdrawn from the tuberculosis service, that tuberculosis schemes have but little life in them, that sanatorium physicians and patients have become disappointed and depressed, and that the tuberculosis movement lacks soul, aims, organisation, and financial means. This picture is obviously as true as it is gloomy, and in attempting to introduce some patches of bright colour into it, the author has earned the gratitude of many. By dedicating his book to Dr. Varrier-Jones he indicates as clearly as is possible the value he attaches to the Papworth system of treatment by tuberculosis colonies and settlements. But before he comes to this topic the author gives several chapters on such subjects as the prevalence of tuberculosis, infection, and diagnosis. The chapter on the tuberculosis dispensary is short and pithy; the author is well advised in urging medical officers of tuberculosis dispensaries to be more concerned with the discovery of "contacts" than with tuberculin medication. Tuberculin is, like hilum tuberculosis, one of the author's bugaboos; he expresses the hope, which is surely unduly optimistic, that when "the tuberculin man has at last seen the error of his ways the millennium will be in sight." In the chapter on the sanatorium the pertinent question is asked: "Why, in our industrial sanatoria, can we not 'cure consumption' as Brehmer at Görbersdorf and Walther at Nordrach did in private sanatoria, and as many others have done in this country?" Here the author has put his finger on a painful spot. He answers his own question: "One of the reasons is because no attempt has been made to establish a school for the training of the men who ultimately become directors of our public sanatoria." But if such a school were established, who could be found to train the trainers? The author is fortunate in his definition of the primary object of sanatorium treatment, which is "to fit the patient for the occupation in which he was engaged before the onset of his illness." In these few words he shows his distrust of the popular belief that by putting a puny bank-clerk on to the land he will almost automatically become a hardy son of toil. Other useful hints are given with regard to the improvement of sanatorium treatment, one of which is that there should be no time-limit for the duration of treatment in any given case. The chapter on the settlement is a plea for the Papworth system, for the author believes that the solution of some of the great difficulties of the tuberculosis problem lies in "the gradual transformation of the existing sanatoria into settlements on the lines which at Papworth have been shown to be practicable." It is safe to say that no one will agree with all that the author has to say, yet everyone will find much to learn in a book which is full of caustic wit.

Perforated Ulcers.

Les ulcères perforés de l'estomac et du duodénum. By H. Mondor et G. Lauret. Paris: Masson et Cie. 1923. Pp. 186. Fr.10.

This monograph on perforated ulcers of the stomach and duodenum is a good account of the knowledge which has been accumulated to the present day on this subject. After reviewing the ætiology and pathological anatomy, the authors describe the clinical symptoms, laying great stress upon the problem of diagnosis. The most interesting section of the book to the practising surgeon is that which deals with treatment. The authors recognise three methods—namely, simple suture, suture plus gastro-jejunostomy, and resection of the stomach. Of these three methods they consider the most generally useful is the second. They are keenly alive to the drawbacks of combining any other operation with simple suture, but consider that on the whole the best results are obtained by adding a gastro-jejunostomy, especially as they recommend a wide infolding of the ulcer area. However, the relative merits of simple suture and suture with gastro-jejunostomy are well set forth, and from the statistics collected it is not possible to decide which is the safer procedure. As to resection, the authors think that it is too early to form any definite conclusion as to its advisability. They consider that in the hands of special operators it may be a method of choice.

Cancer: Fallacy, Theory, and Fact.

By John Shaw, M.D. Lond. London: George Routledge and Sons, Ltd. 1923. Pp. 184.

In this book Dr. Shaw makes "an earnest appeal to the honour of the medical profession throughout the world" to consider the treatment of cancer "without prejudice at whatever cost it may be to the immediate financial interests of the surgeon." The implication is that surgeons are tempted by greed to maintain a system of therapeutics which they do not believe in, or one, to put the position more pleasantly, whose defaults they are too ignorant to estimate. Dr. Shaw has collected a large number of figures in support of his theory that operation cannot be a rational treatment either of cancer or of precancerous growths. He is profoundly sceptical of the value of cancer research, and states that only one observation made by the Imperial Cancer Research Fund has been of practical aid to mankind—namely, that while cold does not destroy the vitality of the cells of mouse tumours moderate heat does. This observation he has utilised in the treatment of cancerous patients. Dr. Shaw's own thesis is to the effect that the secondary causes of death registered in patients succumbing to cancer are really the primary causes of the cancer, amongst them syphilis, alcoholism, gout, rheumatism, diabetes, Bright's disease, tubercle, and, above all, cardiac insufficiency and other defects of the circulatory system. The diagnosis of cancer having been made by the surgeon, he would like the patient who is averse from operation to be allowed non-operative treatment at the hands of anyone he or she may select who shall have presented prima facie proof of having cured cancer without operation or after operation had failed. Dr. Shaw suggests himself as one who has presented such proof.

PALÆOPATHOLOGY.

The Antiquity of Disease. By R. L. MOODIE. Chicago: University Press. 1923. With 37 figures. Pp. 148. $1.50.

THE author has gathered together the little that is known about the pathological anatomy of fossil animals and adds to this some account of the pathology of primitive peoples. He ranges from healed fractures and an example of osteomyelitis in Permian reptiles to the calcified aorta of King Merneptah, which showed that his heart really was hardened, even if he was not drowned in the Red Sea. For the most part his evidence is derived from the enormous mass of vertebrate material which has been found in Wyoming and elsewhere, and, relating as it does almost exclusively to bones, the picture of ancient pathology which may be derived from it is necessarily very incomplete. The rôle of parasites is specially obscure. The occurrence of bacteria in Devonian strata seems to be well-established and they have been described even in pre-Cambrian rocks. They are to be found in some fossil bones as post-mortem invaders causing sometimes a certain amount of decomposition and structural alteration. In Permian and later reptiles their activities in causing inflammatory changes have been recognised. But if they were at these remote periods the cause of epidemics we can get no evidence to that effect beyond the finding of fossil tsetse flies in the oligocene of Colorado, which suggests that trypanosomes may have played a part in the evolution and succession of the early ungulates. In the last chapter, which deals with the early historic period, the author makes no use of the evidence other than anatomical which tells us something at any rate of epidemic disease, though readers will notice with interest the reproduction of cutaneous leishmaniasis on human faces on pre-Columbian jars in Peru.

The book is badly written, with much needless repetition; its format is in the nearly perfect style of the Science Series of the University of Chicago to which it belongs.

PHYSIOLOGY OF THE NERVOUS SYSTEM.

Methodik der Physiologie des Zentralnervensystems von Wirbeltieren. By WILHELM TRENDELENBURG, Tübingen. (Lfg. 104. Handbuch der Biologischen Arbeitsmethoden. Edited by Prof. E. ABDERHALDEN. Abt. V., Teil 5B, Heft 2.) Berlin: Urban and Schwarzenberg. 1923. Pp. 93 to 372.

THIS valuable article is apparently a new edition of one which appeared some years ago in Tigerstedt's "Handbuch der Physiologischen Methodik." It is brought fully up to date. Many of the contents are extremely technical and give, in great detail, the operative technique for experimental work on all parts of the central nervous system of all classes of vertebrates. This volume, like all the other parts of this stupendous publication which we have seen up to the present, will prove of great value to physiologists working or proposing to work on the subject with which it deals. The author's own knowledge of this special branch, in which he has earned world-wide reputation, is evidently immense, and the literature quoted leads us to think that he has omitted little or nothing of importance. The paper and printing are well up to pre-war standard with the exception of some of the half-tone blocks.

JOURNALS.

BRITISH JOURNAL OF SURGERY.—This journal now enters on its eleventh year, and we are glad to point out that it has been found possible with this number to return to pre-war conditions. The type has been improved, the pages increased to 200 in number, and we are informed that no opportunity will be lost to enhance still further the value of the contents. The present issue shows clearly the care and expense spent in its production, for the numerous and excellent illustrations are of a high order. In this forty-first number Sir D'Arcy Power continues his series of Eponyms, the subject being Pott's Disease of the Spine.—L. R. Braithwaite publishes his Arris and Gale lecture on the Flow of Lymph from the Ileo-Cæcal Angle. His work is based on experimental injections into cæcal lymph glands or the cæcal wall of animals and human beings of a pigment. He shows how the lymph stream from this area flows upwards to glands near the pylorus, and suggests that this has a bearing on the ætiology of gastric and duodenal ulcers.—M. J. Stewart and S. D. Lodge report the following renal abnormalities in 6500 consecutive autopsies, 14 horse-shoe kidneys, 1 unilateral fused kidney, 16 cases of congenital absence of one kidney, and 3 pelvic kidneys.—C. A. Joll discusses metastatic tumours of bone, analysing the nature of the primary growths, the bones affected, and the method of spread. He enters very fully into that most interesting of all bone metastases, those of thyroid origin, in which the gland itself is either normal or the seat of a benign growth.—A. P. Bertwhistle reports a case of depressed fracture over the angular gyrus, and its clinical and radiological localisation.—K. W. Montsarrat describes an operation for hæmorrhoids as practised successfully by himself for three years.—Hamilton Drummond records a case of retrograde intussusception of the small intestine into the stomach after a gastro-jejunostomy, and reviews the 11 cases recorded in the literature.—G. L. Keynes's Hunterian lecture on Chronic Mastitis is reproduced in full. In it he describes the normal structure and function of the breast, and seeks an adequate explanation of the changes found in chronic mastitis. Discarding all previous theories, and pointing out that in non-lactating breasts secretion must normally be balanced by re-absorption, he suggests that irritation due to stagnating secretions and epithelial debris may be the cause of those pathological conditions grouped under the head of chronic mastitis.—H. F. Macauley reports a case of a congenital ileo-cæcal cyst causing an intussusception in a child of six months.—Prof. S. G. Shattock has some illuminating pathological remarks about sarcomata of long bones. Amongst them is a suggestion for the safe removal of pieces of bone tumours for examination by means of a heated borer, the heat preventing malignant cells being grafted in the wound.—Prof. J. E. S. Frazer writes concerning the nomenclature of certain pathological conditions in the neck caused by the remains of vestigial structures. He points out that the terms "branchial" and "branchiogenetic" are inapplicable. He outlines the development of the pharynx and the cervical sinus, and shows that any cystic or fistulous condition in the neck is capable of accurate differentiation and recognition.—A visit to the clinic of Prof. Putti at the Istituto Ortopedico Rizzoli at Bologna is described.—R. Hamilton Russell describes a simple method of operating on femoral herniæ, which does not sound in the least convincing.—E. M. Woodman discusses malignant disease of the upper jaw. He emphasises that the area from which these growths arise is much more extensive than the superior maxilla proper, and, in fact, includes the whole of the air-cell area. He advises a very wide ablation of the affected parts, with no attempt at any plastic repair until all fear of local recurrence can be excluded.—H. P. W. White analyses the factors influencing the time of closure of suprapubic urinary fistulæ following suprapubic prostatectomy.—The following rare or obscure cases are reported: (1) A. G. Timbrell Fisher, a case of Acute Hæmorrhagic Pancreatitis twice in the same patient with recovery; (2) L. R. Braithwaite, a case of Multiple Jejunal Diverticula; (3) C. Hamilton Whiteford, an Unusual Case of Death in Acute Appendicitis; (4) Douglas Drew, Perforation of Meckel's Diverticulum.

Journal of Industrial Hygiene.—July: Attention is drawn by D. C. Parmenter to the value of a health department to a mercantile business; instances are given. Each worker makes about ten visits a year to the department, and the visiting physicians see about 10 per cent. The cost works out at about $4 (18*s.*) per head. The financial benefits are not stated, except that in one case $3000 dollars were saved in one year in accident liability, about $2 a head, apart from other gains.—F. Koelsch discusses metal-fume fever and concludes that fumes of all heavy metals, such as copper, tin, lead, nickel, and mercury, as well as zinc, can cause the symptoms of brass-founder's ague. Zinc is the most usual metal concerned on account of its low boiling point, but if other metals are boiling their fumes cause similar effects.—An article of great interest to accident prevention is contributed by H. D. Kitson and C. Campbell; the authors show by striking diagrams an extremely close relation between the number of accidents and the number of new employees. They conclude that if the number of new employees could be reduced to zero the accidents would be reduced by 75 per cent. Hence efforts to reduce labour turnover and give more instruction to new workers are strongly advocated.—Danger from hydrocyanic acid gas arises in certain metallurgical and chemical operations, and in fumigating buildings, ships, and green-houses. S. H. Katz and E. S. Longfellow have developed convenient test papers for detecting the gas, which give estimations over a range of 25 to 1000 parts of the gas per million parts of air within 20 per cent. of those found by chemical analysis. Atmospheres containing 100 parts per million or over should be considered dangerous. ——August: The main article, an important one, refers to carbon monoxide asphyxia and artificial respiration; it deals with laboratory research carried out by C. K. Drinker, K. R. Drinker, L. A. Shaw, and A. C. Redfield. They found that excessive artificial respiration by positive pressure apparatus does not harm the heart; but infected mucus, &c., may be carried into air-passages and set up broncho-pneumonia. While manual methods cannot be evaluated, the Schäfer method is probably more efficacious than is usually believed. A useful bibliography is given.—Next comes the final report of the Commission on Carbon Dioxide Asphyxia, in which the Schäfer method is recommended as against any positive pressure apparatus, which may do actual harm. The use of the new carbon-dioxide-oxygen inhalations developed by Henderson and Haggard is recommended as a specific remedy whenever available.—J. Fine reports upon the phagocytosis of lead compounds and their influence upon the activity of the leucocyte. He found metallic lead less readily phagocytised than basic lead carbonate; that soluble lead injures leucocytes and diminishes their ability to engulf carbon particles; that metallic lead has a similar but less pronounced effect; and that the rate of phagocytosis of metallic lead is of the same low order of magnitude as that of quartz.

Reports and Analytical Records.

BIRMO: SWISS NATURAL BITTER WATER.

(A. G. Pluss, 9, Noel-street, W. 1.)

This water is stated to occur naturally at Birmenstorf, Canton Aargau, Switzerland. When analysed the following results were obtained, expressed as grammes per litre:—

Sodium chloride ..	2·26	Calcium carbonate	0·6
Sodium sulphate ..	11·38	Silica	0·02
Magnesium sulphate	17·2		
			31·46

The water had a specific gravity of 1029·74 (water = 1000) and was very faintly alkaline in reaction. Birmo is an aperient water which has been known for the last 80 years. It is of the Hunyadi János type (The Lancet, 1922, ii., 1284), but somewhat less concentrated. The magnesium sulphate is in excess of the sodium sulphate as the above figures show, whereas in Hunyadi János these constituents are present in equal amounts. Magnesium sulphate is one of the most powerful of the saline purgatives, its positive and negative ions both contributing to this result. It produces no irritation, as the increased peristalsis results from distension due to the presence of an increased quantity of fluid. Sodium sulphate is practically not absorbed, and it thus possesses the property of abstracting liquid from the tissues of the intestinal walls and acting as a saline cathartic. Saline cathartics, except under special conditions such as dropsy, are best given in dilute solutions as in the natural mineral waters.

IODINE MEDOL (ANTISEPTIC UNGUENTUM).

(Pearson's Antiseptic Co., Ltd., 61, Mark-lane, E.C. 3.)

This preparation is claimed to be a non-toxic and non-irritant antiseptic ointment prepared from oxygenated hydrocarbon in combination with 1 per cent. iodine and 5 per cent. hycol. By the term "oxygenated hydrocarbon" presumably is meant the mixture of liquid paraffin and oleic acid referred to in the British Pharmaceutical Codex under the name "Parogenum." Hycol is a disinfectant of the creosote or cresol type. When analysed the preparation was found to contain 0·8 per cent. of iodine which is in fair agreement with the claim of the manufacturers. Iodine medol will no doubt be found useful as a means of applying iodine in a readily penetrable form in conjunction with an antiseptic.

PHLOGETAN.

(Dick Coates and Co., 41, Great Tower-street, London, E.C. 3; J. T. Roberts, 23, Panmuir-street, Dundee.)

Reference has been made in these columns on previous occasions to phlogetan therapy, and we have now received from the British agents of the Czecho-Slovakian laboratories samples of the latest method of preparation and evidence of the increasing interest taken by the medical profession in the drug. Phlogetan is a derivative of albuminoid bodies containing nucleo-protein, and is issued in hermetically sealed ampoules for intramuscular or subcutaneous injection. It was first brought to the attention of the medical public by Prof. Oskar Fischer, of Prague, who reported favourable results in tabes, since when the range of utility has been extended by other observers. There seems no doubt that good results have been obtained in association with the usual treatments for the condition, but the directions for administration, which are sent with the preparation, should be carefully followed.

VITANIUM.

(Vitanium Company, Link Hall, Sandhurst, Kent. Agents: May, Roberts, and Co., Ltd., and Edwards and Son.)

We have received a sample of "Vitanium," a liquid stated to possess the property of converting caseinogen into a non-coagulable protein, thus making cow's milk more digestible to infants. The preparation consists of sodium saccharate with a trace of sodium albuminate, the action on caseinogen being one of hydrolysis. It has been specially recommended for adults who have found cow's milk indigestible or constipating, while they could readily digest milk which does not curdle. To prepare milk for the infant the instruction is, "Take half a pint of milk in the morning, add one teaspoonful of sugar, half a teaspoonful of Vitanium, and boil." In the case of Grade A milk boiling is not considered necessary. For adults one teaspoonful of Vitanium is added to each pint of milk and well stirred in. The preparation can be used for any age and for any length of time without harm.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 15, 1923.

HEADACHE.

AMONG minor nervous afflictions to which the flesh is heir headache enjoys an unenviable prominence. It belongs to a group of ailments the annoyance occasioned by which is not diminished because they may interfere but slightly with the working capacity of the individual. If some bouts do, in fact, lead to prostration, others receive no more notice than a casual comment that the sufferer is having "one of her headaches." Her headaches! There is scant sympathy in the possessive, as though headache were a thorn in the flesh planted by an inscrutable Providence, to be endured rather than cured. We may call it a minor affliction if we will, scarcely enough, sometimes, to arrest attention, still less compel investigation, but the dictum of BRISSAUD is in this respect peculiarly applicable: "rien ne serait moins scientifique que d'établir entre les problèmes médicaux une hiérarchie basée sur la gravité des symptômes; pronostic à part, il n'y a ni grandes ni petites maladies."

For all its banality, headache is a symptom the causation of which is frequently as obscure as its exact localisation is elusive. Last week in our own columns Mr. A. B. PAVEY-SMITH, of the Royal Bath Hospital, Harrogate, dissatisfied with what he has found in most books of reference, came forward with a classification of the "starting-point of the pain" into three main groups—viz., intracranial, cranial, and extracranial. This division, it should be understood, is not concerned with the diseases of which headache may be a symptom, but with the actual sites of the pain-causing lesion. How are these sites to be determined? The observer has at his disposal two criteria, the subjective and the objective—what the patient feels, and what the pathologist finds. He can, further, utilise the information furnished by the histologist as to the tissues in which sensory nerve-endings can be demonstrated, and by the physiologist as to the appropriate stimuli for the awakening of afferent impulses to the sensorium. Unfortunately it must frequently happen that he has to rely on the subjective data only, the pathological condition being uncertain and its localisation indeterminate. Further, it is clear, as indeed Mr. PAVEY-SMITH admits, that an intracranial change, giving rise to an "intracranial headache," may be brought about by extracranial lesions; disease may affect simultaneously more than one site wherein pain may originate; and in not a few instances the correlation of the pathological condition with the specific tissues in which is situated the presumed "lesion" causing the pain must be a matter of considerable difficulty. Mr. PAVEY-SMITH'S proposed classification is symptomatologically topographical but not ætiological, and in spite of its ingenuity not a little is purely speculative—a comment that might be passed on every classification since the era of Galen. The father of medicine, it may be recalled, believed the seat of the pain in headache might be (1) in the arteries and veins of the brain or in the meninges, (2) in the pericranium, and (3) in the temporal muscle—e.g., in hemicrania. He distinguished between internal and external headache, between pain situated in intracranial, and that in extracranial structures, and, according to Dr. HARRY CAMPBELL, even claimed to diagnose one from the other. How much of his contention was a lucky guess and how much based on objective considerations it would be difficult for us now to determine.

We know, of course, that the pain of headache exists only in consciousness, and while we shall not attempt to "localise" the latter we may, for the sake of argument, assume that the appreciation of painful stimuli depends on the integrity of the sensory cortex. Whether, as a fact, it is at the thalamic or the cortical level that impulses of the physiological order are transformed into painful sensations of the psychical order is immaterial for the moment. Wherever the change, we do not suppose the sensation is there "localised" by the psychologist. Painful sensations are, however, "referred" by consciousness to such and such parts of the head; they appear with some sort of localising sign. This can rarely if ever be so definite as to enable the patient subjectively to refer the sensation to an intracranial, cranial, or extracranial seat; a purely topical localisation (frontal, vertical, occipital, &c.) may be accepted by the observer, but we should be somewhat sceptical of the nicety of introspection which would distinguish, for an instance, between bone and meninges, or between scalp and bone. We even are more tolerant of the symptomatological hyperboles of the neurasthenic, who declares he feels "as if his brains were being stirred about by a red-hot poker," than we are of any attempt on subjective grounds to differentiate dura from scalp as an algogenic centre. There are certain generalisations, derived from the statements of many headache victims who have been able to regard their infirmity in a detached way, beyond which it seems unwise to pass. Thus in migraine the headache appears to be largely extracranial, though Mr. PAVEY-SMITH, on the other hand, places the "starting-point" of the pain in the sensory cortex; similarly, in the variety known as nodular or indurative headache the individual concerned can usually locate the seat of the pain in extracranial structures. In cases in which the cephalalgia is accompanied by tenderness of the scalp an extracranial origin will be assumed, incorrect though this may be from the physiological viewpoint. In short, so little reliance can be placed on the subjective criterion that neither symptomatologically nor ætiologically can it furnish useful information.

The difficulty facing the clinician who depends solely on the findings of the pathologist is no less real. Headache associated with cerebral tumour, as an example, exhibits no constant relation to the site, size, or nature of the neoplasm. Has the headache of cerebral syphilis a meningeal, vascular, or parenchymatous "starting-point"? It is doubtless "intracranial," but more precision is desirable, if it can be attained. There is evidence apparently supporting the view of the insensibility of the cerebral cortex itself, but we are not sure that the stimuli hitherto applied are those to which it is physiologically capable of responding. Visceral pain, it would appear, is caused by the stretching of hollow viscera, but not by bruising or cutting. The dura probably reacts to stretching or distension; does its inflammation, per se, originate pain, or must the former or some other factor also come into play? Such questions will not be readily answered until a larger number of experimental data, preferably derived from observations on man, have accumulated. From quite another standpoint all cranial pain must originate in stimulation of the end-organs of the trigeminal nerve, or of the upper two cervical dorsal roots, or, conceivably, of sympathetic afferents reaching sentient centres otherwise, and further localisation might seem otiose. Yet the "central pains" of thalamic lesions must not be forgotten, nor the topoalgia of hysteria and the "psychalgia" of other patients vaguely classed as "functional." The twin problems of the ætiology and localisation of headache call for much more examination, it will be seen, and Mr. Pavey-Smith's contribution is a welcome addition to a difficult subject.

◆

LABORATORY DIAGNOSIS OF SYPHILIS.

Many workers in the field of pathology have endeavoured to simplify the original Wassermann technique with its five variable constituents. Some of these attempts have resulted in useful modifications, but on the whole the short cuts introduced for this purpose have resulted rather in a loss of accuracy than in any real saving of labour, or an increased simplicity in the performance of the test. As a consequence the unreliable results which not infrequently come from the hands of those who are attracted by the ease of such modifications as consist in relying upon the natural amboceptor or complement in the patients' serum have brought a certain amount of criticism upon this really trustworthy aid to clinical diagnosis. The precipitation test, first put upon a practical basis by Sachs and Georgi, and which has been previously referred to in our columns,[1] differs essentially from these less reputable modifications of the Wassermann method in placing the reading of the test at an earlier stage, when a visible precipitate has been formed by the interaction of antigen and the patient's serum in positive cases—a precipitate which it is widely held exists in a less obvious form, and is detected by a biochemical method, in the Wassermann technique. A modification of this test was described in The Lancet in 1921 by G. Dreyer and H. K. Ward, and designated by them the Sigma Reaction[2]; this test has since been utilised by a number of workers with very satisfactory results. Recently a comparison of the results given by Prof. Dreyer's method with those obtained by the Wassermann test has been instituted by the Medical Research Council, who have embodied their findings in Special Report No. 78. In this publication are given the results of three independent sets of investigations: a special inquiry, undertaken on behalf of the Council by Prof. Dreyer and Dr. Ward in collaboration with Prof. J. McIntosh and Dr. P. Fildes, and two further independent researches, on larger series of cases, carried out by Prof. Adrian Stokes and Dr. Wigham in Dublin, and by Drs. Thomas Houston, Boyd Campbell, Smyth, Rankin, and Hall in Belfast. The results of these two latter inquiries have been previously made public and are reproduced in the present report. These three sets of investigations are thus complementary, although distinct from one another. If, however, we summarise their combined statistics we find that in all 3651 sera have been examined, and that in 3430 of these the results of the two tests are in agreement. There is therefore left a set of 321 cases, about 9 per cent. of the total, in which the results of the two tests differ. It should be noted in this connexion that in the Dublin figures, which constitute the largest series of the three and include 1515 cases, the percentage divergence is as low as four.

The general agreement of the two tests is therefore abundantly evident and needs no emphasising, but it is very necessary to examine as critically as possible the reasons for such divergences as exist and to estimate, as far as we can, which test speaks with the greater truth. The details of individual discrepancies can only be learned by laborious wading through some 100 pages of tabulated cases, but the clinician may take comfort from the fact that it is mainly in the borderline cases—early primaries, or treated syphilis, where the serum reactions are appearing or fading—that such discrepancies arise, and in these conditions difficulties in diagnosis are not usual. Prof. Dreyer expresses his results in arbitrary units of his own invention, and considers anything over 1·5 units to indicate a positive result. The sigma test, like all serum tests for syphilis, is a quantitative one, a reaction of some degree being probably obtainable with most sera, but only appearing in a sufficient intensity to be readily perceptible by current methods in the case of serum from syphilitics, and it may well be that the figure of 1·5 is too low. If this be so many of the noted discrepancies will disappear and the agreement of the tests will be yet more striking. On the other important question as to which test is most likely to give accurate information in the few cases of undoubted active syphilis where discrepancies arise we have not sufficient information to dogmatise, but it is evident that sometimes the one and sometimes the other may give a true result—a finding which is occasionally seen where different Wassermann techniques are employed simultaneously to test the same serum. The decision as to which test to adopt is almost a personal one for individual pathologists. The flocculation test has the great advantage that it dispenses with three of the variable and unstable factors in the Wassermann reaction—hæmolysin, complement, and red cells—but as used by Prof. Dreyer and his colleagues it is undoubtedly laborious and the use of drops as units of measurement is not likely to appeal to the majority of laboratory workers; it is, however, likely to be of especial use to the man who has a few tests to carry out or who does them at long intervals The Wassermann reaction at the present time is more rapid in performance and more easy to read—considerations which are of great importance in institutes where many tests are carried out each day. We think, however, that the precipitation test is capable of further simplification, and that in the not distant future it will probably replace the more complicated Wassermann. The whole gist of the results of many investigators upon the comparative values of these tests, which have been prosecuted now for three or four years, is that in the hands of a competent operator both are equally reliable as diagnostic aids to the practising physician.

◆

WHAT THE PUBLIC HEALTH SERVICE DOES FOR THE PUBLIC.

The importance of education of the public as a means of improving the health of its constituent members is becoming more fully realised, and the advance in efforts to this end has been especially marked in recent years. The democratisation of government, both central and peripheral, and the fundamental fact that government now means control by elected persons who are non-experts, but who have or can have experts to advise them, necessitate enlightenment and persuasion of the general public if advance and reform are to be secured. Compulsion can only succeed in compelling—except possibly for a short period and in exceptional circumstances—provided it has behind it the preponderant opinion of the public who may be liable to compulsion. Even then, as the experience of recent years has shown, a persistent though small minority may make a particular department of control impracticable; and we are obliged, therefore, to add the possibility of converting the minority into accord with the majority as an essential element of the application of compulsory measures. When this is secured compulsion merely means the organised expression of the will of the community. These considerations emphasise the importance of efforts for the enlightenment of the public in regard to public health work. In this respect our American friends have given us much valuable leading, and although occasionally measures of publicity in some areas have been extravagant enough to call forth caustic strictures from Dr. CHAS. V. CHAPIN, one of the greatest of American sanitarians, on the whole it can be said that great skill has been shown in convincing the public of the need of new departures and in persuading them to adopt them. This has been strikingly evident in recent successful efforts in several large cities to immunise a large proportion of the children against diphtheria. Of all measures for education of the public none is equal in permanent value to instruction of school-children, carried out on rational lines, and from that point of view we welcome the opportunity to quote in another column extracts from a recent series of draft articles sent to editors of public journals in the United States by the Acting Surgeon-General of the Federal Public Health Service, and intended to be read by scholars in upper grade and high schools. Similar efforts have been made on a small scale in this country, but none, so far as we are aware, are so systematic and complete as the one under review, and it is for this reason that we draw attention to the present example of wholesome propaganda.

HOSPITAL CONTRIBUTORY SCHEMES.

THE result of a questionnaire issued by the Voluntary Hospitals Commission as to the methods adopted in various areas to obtain contributions is, on the whole, disappointing. Particulars were received of 72 contributory schemes, affecting 102 hospitals, and a digest of the information available is now issued in a statement [1] for the benefit of local committees and the hospitals in their areas. It is disappointing mainly because the variety of local conditions, reflected in the variety of methods that have been adopted for working contributory schemes, is so great and the schemes in most cases of such recent origin and incomplete development that few lessons of general application are yet available.

Certain obvious points most schemes have in common—for example, reliance for contributions mainly upon deductions from wages. This can, of course, only be effected with the full consent of the wage-earners themselves and with the active coöperation of the employers or, in a few cases, of a voluntary collector at the works. In some instances the employers add a contribution of their own. The method of collection in a rural area presents considerable difficulty, special arrangements having to be made to reach the farmers. Applications and contributions forwarded through the post are not likely to lead to such good results as a scheme worked through group and village committees, the contributions being collected by a volunteer in every village. The collection of regular contributions from the "self employer" presents a special difficulty. They can be reached by a personal canvass in house-to-house collections, or by leaving a collecting book or box which is called for periodically. As to the amount of contributions, the sum payable each week varies from 1*d.* to 3*d.* a week on a fixed basis, or on some graded scale as 1*d.* in the £ of wages. In the simplest forms of contributory schemes the whole of the contributions are paid to the hospital and are allocated to meet maintenance expenditure. In a number of schemes, however, the hospital does not take the whole of the amount subscribed, but some allocation is made to other services—a percentage going, for example, to convalescent homes, nursing associations, and, in one instance, to dental services.

The inducement to be held out in order to attract contributors is a difficult feature in framing a contributory scheme. The majority of hospitals have been careful to avoid holding out any inducement that would bind them in a contractual obligation. There are very few instances in which anything approaching an insurance scheme has been attempted, but in one or two such cases the hospital authorities have guaranteed to all their contributors certain definite benefits. In one scheme the promoters have guaranteed free maintenance in any general hospital and in any convalescent home when required. In other cases the promoters have guaranteed immediate admission and free treatment for their contributors. In others the league or the association which works the contributory scheme guarantees to pay to the hospital a fixed sum per week in respect of each contributor treated. A certain number of schemes, without pledging themselves to the admission and free maintenance of contributors, provide as an inducement certain special benefits which are not available to non-contributors; these include convalescent treatment for the contributors and in some instances for their families, the benefit of specialist services for eye and ear cases and gynæcological cases, special orthopædic treatment, facilities for obtaining surgical appliances and spectacles at reduced fees, and assistance for dental treatment. A common form of inducement is the simple practice whereby contributors or their dependents when admitted are not asked, as are other patients, by the almoners to make a donation to the hospital. The majority of the hospitals, however, promise no special privileges, but rely upon the charitable instinct of the public, maintaining the principle that the necessitous poor and the medically urgent cases must have the first call upon the resources of the hospital. Subject to that, the contributors in practice get facilities for admission and in many instances are not asked to make any further donation to the hospital. It is noteworthy that of all the schemes examined only four have indicated that payments by patients have diminished as a result of the operation of such a scheme. Few schemes do not make some provision for representation of the workpeople contributing on the governing body of hospitals, but the nature of such provision varies from representation on the board of governors only to eligibility for election to the committee of management and the house committee. For reasons which we indicated in commenting on the Sheffield scheme last week this question may ultimately be of extreme importance. The promoters of contributory schemes were invited to state in their replies to the questionnaire any special features which they considered to have contributed to the success of their scheme; the replies have not revealed any one dominant factor as ensuring success. This is not surprising, since the personality of those stimulating the work in any area is probably the weightiest factor and there are no scales whereby this may be compared.

Careful study of the report leaves the impression that the present schemes are transient in conception and execution, and that those who rely least on the detached charitable instincts of the public (which can still manifest itself on the old lines) and most on the sense of responsibility and local pride which it is possible to awaken in those who not only support but help to run their own hospitals, will ultimately prevail.

Annotations.

"Ne quid nimis."

THE LONDON MEDICAL SCHOOLS.

We have received note of formal opening ceremonies at four of the medical schools. The winter session at the Middlesex Hospital will open on Oct. 2nd at 3 P.M. at the Scala Theatre, Charlotte-street, W. 1, when Mr. Somerville Hastings will give an address on Team Work in Nature, and Princess Alice, Countess of Athlone, will distribute the prizes. The annual dinner will be held the same evening at 7.30 P.M. at the Trocadero Restaurant, Sir John Bland-Sutton presiding. St. George's Hospital Medical School will be opened on Monday, Oct. 1st, at 3 P.M., when Mr. E. B. Turner will deliver the inaugural address at the Medical School. King's College Hospital Medical School will have a formal opening on Wednesday, Oct. 3rd, at 2.30 P.M., when Mr. H. J. Waring, Vice-Chancellor of the University of London, will deliver the address, Lord Hambleden presiding. The annual dinner will be held the same evening, 7 for 7.30 P.M., at the Connaught Rooms, Great Queen-street, with Dr. Arthur Whitfield in the chair. Sir Humphry Rolleston will deliver the inaugural address at the opening of the London School of Medicine for Women on Oct. 1st at 3.30 P.M. We are informed that St. Bartholomew's, Guy's, St. Mary's, St. Thomas's, and University College Medical Schools are having no formal opening this year. St. Thomas's old students' dinner will take place on Oct. 26th, 7 for 7.30 P.M. at Princes' Restaurant, Piccadilly, Mr. W. H. Battle presiding. The annual dinner of past and present students of St. Mary's Hospital Medical School will be held at the Connaught Rooms on Oct. 1st, at 7 P.M., Mr. V. Warren Low presiding.

THE ORIGIN AND PREVENTION OF ANTHRAX.

Anthrax in its causation and prevention is essentially an occupational problem, at least in industrial countries. Study of its prevalence in Germany[1] during the past decade indicates how it originates and at the same time the lines which must be pursued to eradicate it.

Notified Cases of Anthrax.

Year.	Animals.	Human beings.
1912	6283	274
1913	6816	224
1918	1002	29
1919	743	18

Clearly the chief source of infection both for animals and man is raw material imported from abroad, the supply of which was largely cut off during the war. From 1910 to 1921, out of 1458 cases about one-half (746) occurred among those employed in agriculture, a higher proportion than occurs in this country. When the remaining cases are distributed among the three main industries concerned a great difference is found between Germany and Great Britain; the difference is due no doubt to the comparatively small woollen industry in Germany.

	Number of cases, 1910–21.	
Industry.	Germany.	Great Britain.
Hides and skins	538	198
Hair and bristles	113	60
Wool	4	443

Great Britain has already led the way in establishing a Government disinfecting station at Liverpool for dealing with infected wool. Germany has now to come to grips with her particular problem, the disinfection of imported hides and skins. Among tanyard workers the source of infection was traced in 335 cases, of which only 19 were due to home hides. Anthrax in home animals arises chiefly from infection carried on to pasture land by waste water from tanyards, so that disinfection of imported material would presumably eradicate the disease.

Three disinfecting processes are known[2]: (1) the Seymour-Jones process, in which the hides are treated with a solution of 0·02 per cent. chloride of mercury and 0·9 per cent. formic acid; (2) the pickling process, in which a solution of 1 to 2 per cent. hydrochloric acid and 10 per cent. sodium chloride is used at a temperature of 20° to 40° C.; and (3) the lye process, the basis of which is a 0·5 per cent. soda lye with 1 to 10 per cent. sodium chloride. The two last are considered better than the first; but each has its special advantages. Pickling takes place before liming and treated hides can be salted and kept. The lye process may be combined with liming or softening, but hides treated are unsuitable for keeping; hence while valuable at tanyards, it is not suited for separate disinfecting stations. The next important decision to be arrived at is whether disinfection, which has been proved to be practicable, should take place in stations at the principal ports of import or in the tanyards themselves. Dr. H. Leymann rather favours disinfection at the tanyard. Certainly all suspected wool on import can be more easily passed through our disinfection station at Liverpool than could hides and skins coming into Germany by a number of channels be directed through a few stations; expense and hindrance to commerce would be entailed, but more certain disinfection would be ensured.

LILLIPUTIAN TUBERCULIN DOSAGE.

In *Paris Médical* for August 18th there is a paper by Prof. J. J. Viton, of Buenos Aires, who describes what he calls a novel method for diagnosing and treating tuberculosis with tuberculin. He has tested his theories for nine years and still writes of them with enthusiasm. As he points out, Koch attempted to diagnose tuberculosis by injecting a large enough dose of tuberculin to provoke a febrile reaction and other signs and symptoms indicative of a temporary exacerbation of the disease. Prof. Viton injects an infinitesimal quantity of tuberculin—he frankly calls it a fantastically small quantity—and instead of getting a temporary exacerbation or aggravation of the disease he achieves marked improvement in all, or almost all, the symptoms from which the patient was suffering. He takes Koch's undiluted tuberculin or a preparation resembling the tuberculin of Denys, and dilutes with a 0·25 per cent. aqueous solution of carbolic acid till he arrives at a dilution of 1 in 1,000,000. This is his starting-point or strongest dilution which he calls A. By repeating the dilutions he ultimately gets to a dilution of 1 in 1,000,000,000,000,000,000,000,000,000 and even higher dilutions, and he calls these dilutions B. C. D. . . . exhausting all the letters of the alphabet. When, in a case of pulmonary tuberculosis with tubercle bacilli in the sputum and signs of progress of the disease, with or without fever, an R. S. T. or higher dilution of tuberculin is injected, the fever, cough, and expectoration diminish, the patient sleeps and eats better, and his general condition is improved. This response occurs 10 to 15 hours after the injection of 0·25 c.cm. of the highly diluted tuberculin, and the beneficial response is of diagnostic as well as therapeutic value. Prof. Viton classifies his patients according as they are (1) tolerant, (2) sensitive, (3) very sensitive, or (4) hypersensitive. In the first class, suitable for dilutions A to F, are chronic or subacute cases of rheumatism of Poncet's type, neuralgia, neuritis, dyspepsia, and the like. In the second class, suitable for dilutions G to L, are early apyrexial forms of tuberculosis, including tuberculosis of the skin and cases of obscure dyspepsia. In the third class, suitable for dilutions M to R, are cases of early subfebrile tuberculosis, anæmia of obscure origin, and neuro-muscular asthenia. In the fourth class, suitable for dilutions S to Z, are febrile cases of pulmonary and other forms of tuberculosis. If an unfavourable effect is obtained with a certain dilution, it is evidently too strong and a higher dilution must be tried. The good effects obtained with a high dilution last for a variable period, from 1 to 30 days or more. When the good effects begin to wear off an injection of a slightly stronger dilution is given, and the improvement which follows lasts as long as, and often longer than, that observed after the first injection. Prof. Viton does not say whether he has or has not carried out control tests with a 0·25 per cent. solution of carbolic acid alone.

THE LONDON CRIPPLES' FRIEND.

Sir William Treloar did not long survive his eightieth birthday when occasion was taken to celebrate the work on behalf of London crippled children to which he devoted his life. His last public appearance was at the Mansion House on Feb. 21st, when Lord Balfour handed him a substantial cheque for the Alton hospitals. We recalled on this occasion the fact that Treloar accepted the mayoralty in 1906–7 solely in his desire to help the children of the metropolis. Realising, as few laymen have realised, that a large proportion—Treloar himself put it at nine-tenths— of the crippledom of this country is caused by tuberculosis engendered by bad air, bad food, and slum surroundings, he vowed to establish a hospital for children crippled by tuberculosis and to collect for this purpose £60,000 during his mayoral year. The hospitals at Alton Park and Hayling Island which bear his name have put some thousands of children in the way of complete economic recovery, and have done more in setting a standard for similar treatment elsewhere. Of late years Treloar had lived principally at one or other of these hospitals in quiet enjoyment of the realisation of his youthful dreams. He will need no other monument.

EFFECTS OF A RESTRICTED DIET ON RATS.

Some of the effects of a restricted diet have been studied by James Rollin Slonaker and Thomas A. Card.[1] Their studies have been continued over a period of eight years on rats, some of which were fed on a so-called vegetable diet, and others on a similar diet with the addition of a certain amount of animal protein—called an omnivorous diet. The effect on growth is of interest. The maximal weight of the males fed on the restricted diet was 35 per cent. less, and that of the females 25–28 per cent. less, than that of the corresponding control animals. The maximum weight was reached considerably earlier on the omnivorous diet. The duration of life was shorter on the restricted diet, but was prolonged when food containing animal protein was added to the diet. Moreover, the offspring of the rats fed on the restricted diet were less in weight than those of the controls—the newborn males being 18 per cent. and the females 14·5 per cent. less. The effects of the restricted diet became more and more pronounced until they reached the age of 250 days. The males were then 60 g., the females 25 g. behind the controls. The effects on pubescence and menopause were striking. In young rats the onset of sexual maturity was considerably delayed on a purely vegetable diet, as compared with normally nourished omnivorous animals, and this delay was the more evident the earlier the animals were fed on the vegetable diet, and the effect was more marked in the males than in the females. The period of menopause was not much delayed, but the period of sexual activity was shorter in those animals fed on the one kind of food. Moreover, on the restricted diet a considerable number of the animals remained sterile, and this was the case more frequently in the females than in the males. The longer the feeding on the one kind of food is continued the more marked were its effects. If to the vegetable diet animal food was added, the animals, as regards onset of sexual maturity, menopause, and duration of sexual activity, approach nearer these conditions in the normal animal, and the number of sterile animals was less. The effect on the number of litters and young born was also striking. On the purely vegetable diet a considerable number of the animals were impotent; their capacity for reproduction was less and disappeared in the third generation. Animals which were still capable of reproduction recovered on an omnivorous diet and manifested again almost normal relations. Of 70 pairs fed on omnivorous diet the number of litters was 3·28 per pair, the total number of young 15·7 per pair, and the number at each litter 4·77. The corresponding number in 69 pairs confined to a vegetable diet were 1·58, 7·8, and 4·68. The corresponding results on a number of pairs, where one parent was fed omnivorously and the other on a vegetable diet were 2·0, 8·82, and 4·41. If the parents and young alike were kept on vegetable diet the numbers were 1·82, 6·64, and 3·65, and in corresponding animals fed on the omnivorous diet the numbers were 2·64, 10·36, and 3·93. These effects on growth and sexual maturity of a reduction of animal protein in food are certainly noteworthy.

INFANT MORTALITY FROM TUBERCULOSIS.

The Registrar-General's annual review for 1921—a preliminary summary of which appears on p. 582—includes an important study of the course of the national death-rate from tuberculosis, to which special attention may be drawn. The study teems with difficulty, as there are known to have been changes in custom in certification and an important change in the classification of "hydrocephalus" which when not described as "acute," has since 1901 been excluded from tuberculosis. It appears, however, that if all changes in classification were eliminated the death-rate from tubercle of the nervous system (practically all tuberculous meningitis) in 1921 would be increased only from 0·70 to 0·92 per 1000 births, as compared with 3·03 in 1876–80. Tabes mesenterica, now rarely returned as a cause of death, up to 1901 was the commonest form of record for deaths from abdominal tubercle; and it is highly probable that a large share of the reduction in the death-rate from tubercle of the intestines and peritoneum—from 4·51 in 1876–80 to 0·45 in 1921—is due to the fact that in past years non-tuberculous conditions were often returned as tubercle. Tubercle of other sites has declined as a cause of death in the same period from 2·06 to 0·39 and of all sites in the aggregate from 9·29 to 1·54 per 1000 births. Valuable diagrams given in the report enable the course of events for quinquennial periods from 1861–65 to 1916–20 to be traced, and it is important to note the totally different courses followed by the mortalities from pulmonary and from non-pulmonary tuberculosis. The decreased death-rate from pulmonary tuberculosis has gone on for a long series of years, and since 1866 has occurred at a remarkably constant rate; whereas, the total rate from non-pulmonary tuberculosis is changed but little until after 1891 when a very rapid decline began. It appears highly probable that the explanation lies, as is suggested in this review, partially in the fact that with the greater sense of responsibility following on Koch's publication of the discovery of the tubercle bacillus in 1882, there was no balance of over-statement to be eliminated in the case of phthisis, whereas there was a large balance of overstatement in the case of non-pulmonary tuberculosis, both infantile and at all ages.

There would appear, however, to be a real decrease in infantile tuberculosis. For, as is pointed out in the review, infant mortality in general has declined enormously, and tubercle might be expected to have shared in this decline. There has also been increased protection of infants from exposure to infection by sputum, in connexion with institutional treatment of open cases of phthisis and otherwise. Furthermore, so far as tuberculous meningitis is concerned, if deaths formerly attributed erroneously to this disease are no longer so attributed, we might expect increased mortality from "meningitis," but there has, on the contrary, been decreased registration of deaths under this heading. The general conclusion must be that the decline shown in the statistics has both fictitious and real constituents. The subject is one of great importance, as bearing on the estimation of success of anti-tuberculosis work. Events since the beginning of the present century are especially instructive; and there is reasonable ground for believing that infection of infants and young children with tubercle bacilli in massive dosage or of frequent occurrence is diminishing with the development of hygienic precautions and the general education of the public in connexion with the administrative control of tuberculosis.

THE DEVELOPMENT OF FILARIA RECONDITA.

BULLETIN No. 144[1] of the Agricultural Research Institute at Pusa contains observations on the morphology and life-cycle of *Filaria recondita* Grassi, by M. Anant Narayau Rao, assistant professor of agriculture in the Madras Veterinary College. The material on which these observations are based was obtained from the in-patients in the dog ward of the College Hospital. The microfilariæ or embryos are sheathless, 221–225 μ in length, with a breadth of 4½–5μ, and in common with microfilariæ of other species they shoot out from the cephalic extremity a minute spine. An interesting point which the author ascertained, a character possessed in common with the embryos of *Filaria bancrofti*, is the habit of nocturnal periodicity. The embryos increased in number in the blood after 7 P.M., were swarming at midnight. Exposure to the sun or exercise reduces the few microfilariæ which can usually be found in the peripheral circulation during the daytime. At autopsy the largest numbers of microfilariæ are found in the lungs. Dogs that have died of this infection show characteristic pathological appearances—all the internal organs were anæmic, while the liver exhibited caseating areas surrounded by a zone of congestion; similar, but less intense, lesions were present in the spleen. The real interest of the paper lies in the fact that the author has traced the full development of this microfilaria in the thoracic muscles of *Culex fatigans*, while he has definitely shown that *Stegomyia* cannot serve as an intermediary host. The development follows that of *F. bancrofti* very closely and the mature larvæ can be demonstrated in the proboscis on the fifteenth day. They measured about 0·5 mm. in length. This work finally disposes of the suggestion of Grassi and Calandruccio that development may take place in various species of flea and tick.

SPONDYLOLISTHESIS.

THE skill, frequency, and financial success with which osteopaths are wont to reduce an imaginary dislocation of the spine are apt to blind us to the fact that there really is such a condition. Since Rokitansky in 1836 published an account of two cases of spondylolisthesis many such cases have been recorded, and by 1890 Neugebauer was able to collect as many as 101 cases from the literature. It is significant and humiliating to the medical profession that the correct diagnosis was made during life only in 47 of these cases; in the remainder the correct diagnosis was deferred to the post-mortem examination. Records such as these may tempt the osteopaths and other Philistines to scoff at this exhibition of orthodoxy, but it would be fair to point out that these mistakes belonged to the pre-Rontgen period, and it is comforting to note that all the 15 cases collected by Neugebauer some years later were diagnosed correctly during life. In *Norsk Magazin for Lægevidenskaben* for July Dr. Sofus Wideröe, one of the surgeons attached to the Communal Hospital of Christiania, has recorded two instructive cases of forward and downward displacement of the fifth lumbar vertebra in relation to the sacrum. In both cases complete recovery was effected by immobilisation of the affected parts by Hibb's bone-grafting operation which established bony union between the lowest lumbar vertebra and the sacrum. The first case was of special interest, as it clearly showed the mechanism of this dislocation and the diagnostic pitfalls it may dig. The patient was a girl aged 18, who, two years earlier, was indulging in horse-play with a strong boy standing behind her and arching her body forcibly backwards. She felt a sudden painful snap in the back and had to stop playing, but she was able to walk home. The next two years were passed in pain and invalidism; when she attempted to walk she was subject to attacks of violent pain in the back, making her collapse on the ground. Pott's disease was suspected, but a skiagram showed no sign of it. Treatment for two months by extension rid her temporarily of her pain, but after she had been symptom-free for about 11 months an attempt to return to office work provoked a relapse, and she went from one physician to another, being treated for rheumatism and other hypothetical complaints, and becoming steadily worse. On admission to Dr. Wideröe's hospital she showed definite lordosis of the lower lumbar spine, which became painful when she attempted to stand as straight as a recruit. A skiagram taken in the frontal plane revealed nothing of interest, but a skiagram taken from one side showed the fifth lumbar vertebra to be displaced forwards, the third lumbar vertebra forming an angle of 80° with the sacrum. The complete recovery effected by Hibb's operation in this and Dr. Wideröe's second case is well worth the notice of surgeons in charge of traumatic spinal cases with obscure symptoms and without the benefits of a skilled X ray examination.

THE RISKS OF THE MECCA PILGRIMAGE.

INTERESTING particulars are given in a recent report[1] of the measures taken to prevent the spread of cholera in Egypt. Before the war the pilgrims leaving Egypt averaged about 13,000 per annum; during the war the number was greatly reduced and now the size of the pilgrimage is gradually increasing. The numbers for the last five years have been: 1916, 1076; 1917, 281; 1918, 464; 1919, 444; 1920, 1657; and 1921, 2956. All the pilgrims were vaccinated against cholera before leaving Suez. The medical officer in charge reported that there were no facilities for hospitalisation of the pilgrims in the Hedjaz, in Jedda and Mecca and that his supply of drugs for the Egyptian pilgrims was exhausted, owing to the importunate demands of the notables of Mecca, before Jedda was reached on the return journey. In consequence the Egyptian Public Health Department is drawing up a scheme for a properly organised system of treatment and hospitalisation for its own pilgrims and hopes that the Governments of other countries from which pilgrims go will do likewise. No epidemics were reported from the Hedjaz during the 1921 pilgrimage. One returning Egyptian pilgrim was found to be suffering from cholera at the quarantine station at Tor. The Egyptian pilgrims were, as usual, carefully traced on their return to Egypt and those who showed any intestinal symptoms whatever had their stools bacteriologicallly examined. No further case of cholera occurred. During the pilgrimage a bacteriologist and a laboratory attendant are sent to the Suez laboratory to carry out the necessary examinations in connexion with returning pilgrims. Patrols are maintained in Sinai and on the Red Sea littoral to prevent Egyptian pilgrims returning by an unauthorised route to escape quarantine. The Sinai patrols intercepted 21 pilgrims. A regulation is in force prohibiting the entry into Egypt of returning non-Egyptian pilgrims, and difficulties arose in 1921 through other Governments having made no shipping arrangements for the return of their nationals to countries north of Suez. Obviously the whole of the precautions of the Egyptian Government with regard to Egyptian pilgrims will be of little avail if foreign returning pilgrims are allowed to trickle through the country uncontrolled. The Governments concerned should either provide direct sea transport or make financial provision for controlled land transport and repatriation of their own nationals. Medical control of a pilgrimage from each country of origin, on the lines of the existing Egyptian arrangements, would do much to reduce the present constant menace to the world's health.

[1] Report of the Ministry of the Interior on the Health of Egypt, 1921.

THE PATHOLOGY OF LEGG'S DISEASE.

THE disease of the hip-joint associated with the names of Legg, Perthes, and Calvé has been recognised as a clinical entity since 1909, but its causation and pathology are still in doubt. The disease is not fatal, nor does it, as a rule, necessitate operative intervention, and therefore material for examination has been difficult to obtain. Histological examination of one case (Fründ) showed that the spongy tissue of the head of the femur was completely necrosed, while the cartilage remained intact and living. Prof. A. Nussbaum,[1] of Bonn, confirms this statement, and has produced exactly the same result in young dogs by division of the blood-vessels supplying the head of the femur. Microscopic examination revealed necrosis of the spongy tissue of the epiphysis, characterised by lack of staining of the nuclei of the bone cells in the marrow and cortex. The cartilage, on the other hand, remained in good condition, as shown by perfect staining of the nuclei and thickening of the cartilage, thus demonstrating that cartilage can live without its direct blood-supply, and must be nourished by the synovial fluid. In healthy well-nourished epiphyses the newly-formed cartilage is ossified by the endochondral type, and growth progresses evenly; but when the circulation is interfered with the columns of cartilage cells are no longer ossified by the ingrowing blood-vessels, but grow irregularly on top of the bone already formed, producing tongues and islands of cartilage dipping down into the spongy tissue. These tongues and islands correspond to the clear areas seen in the X ray. The diminished ossification of the cartilage explains its thickening, which is shown in the X ray by increase in the width of the joint cavity. Later, regeneration of the head takes place by new blood-vessels growing in with connective tissue developed from the synovial membrane. These experiments prove that Legg's disease is due to a primary necrosis of the head of the femur caused by an interference in the blood-supply, the cause of the latter being still unknown. Prof. Nussbaum suggests that the name the disease usually bears on the continent (osteochondritis coxæ juvenilis) is false, and should be replaced by necrosis capitis femoris.

ATMOSPHERIC POLLUTION.

THE eighth report of the Committee for the Investigation of Atmospheric Pollution provides much valuable information obtained from systematic analyses of impurity deposited from the air at about 30 experimental stations in different parts of the country. The first six reports appeared as supplements to THE LANCET; the present report covers observations for the year ended March 31st, 1922. As investigations on these lines have been carried out for a series of years it has been possible in the case of most stations to include in the report a comparison between the deposit collected during the current year and the average results of the past five years. In nearly all stations the quantities deposited during the year were below the average. Comparison between summer and winter deposits show that the summer total was less than the winter in 14, equal in three, and greater in five cases. From the records of Dr. J. S. Owens's automatic instrument figures showing the amount of suspended matter at each hour of the day and night have been prepared for London and Rochdale, and graphs of the average values over long periods indicate the remarkable parallelism between impurity and the periods of activity of domestic fires. Other curves showing the variation of pollution at three London stations on different days of the week bring out the effect of local smoke production on the state of the air. The effect of the coal strike of 1921 upon the maximum amount of suspended impurity in London air is shown in another figure. Experiments in Rochdale to ascertain what proportion of the impurity was produced locally and what was carried there by air currents show that only 15 per cent. of the matter deposited at the centre of the town was brought there by the wind. Dr. Owens's new portable instrument has proved of good use for the rapid collection of suspended atmospheric dust in a suitable form for examination and counting under the highest power of the microscope. Photomicrographs of some typical specimens of impurity magnified up to 2000 diameters are given in the report, and a useful bibliography of the measurement of dust by various methods is added. Special interest attaches to this report owing to the hope that the problem of atmospheric pollution is to receive serious consideration in Parliament in the near future. The Government are pledged to legislate upon the matter, and one of the proposals of the Bill introduced into the House of Lords by Lord Onslow on behalf of the Ministry of Health runs as follows:—

> "The powers of the urban authority . . . shall extend to the making of bye-laws requiring the provision in new buildings *other than private dwelling houses* of such arrangements for heating as are calculated to prevent or reduce the emission of smoke."

This Bill will come before Committee when the House of Lords reassembles in November, and, although it is an earnest of official interest, the measure as drafted falls short of what is regarded by some as essential. At present Government premises enjoy a complete immunity from prosecution as regards nuisances; they should be brought into line with other industrial concerns. Suggested concessions in favour of the iron and steel trades arouse misgiving, for clearly the Bill should retain such advantages as the present law possesses until replaced by something better. The report deals exclusively with measurement and makes no suggestions as to the mitigation of the smoke evil, which is a problem outside the sphere of the Advisory Committee. But exact measurement is an essential step towards improvement and the usefulness of the report cannot be questioned.

THE TRAINING OF MIDWIVES.

THE numbed bewilderment of a flock of prospective midwives being questioned by a member of the honorary staff on an official round has often excited the compassion of the more hardened medical students who may be present at the ordeal. The recommendation by Dr. Janet Campbell in her report on the Training of Midwives (H.M. Stationery Office, 1*s.* 3*d.*) that the minimum training period for unqualified women should be 12 months, and that for trained nurses should be extended from four to six months, will be welcomed by all who have watched these pitiful rounds. For untrained women, who have to gain practical experience of asepsis and antisepsis, as well as to grasp the principles of midwifery, to master in six months the present curriculum is obviously too heavy a task. The examination embraces 17 essential subjects, of which one alone, *the symptoms, mechanism, course, and management of natural labour*, must include a clear conception of the stages of one of the most elaborate physiological processes in the body, almost as puzzling to the clinical student as were the folds of the peritoneum in his dissecting-room days. Dr. Campbell does not advise the extension of the time period without careful consideration of possible disadvantages, which she enumerates, but concludes that it is inevitable if higher standards of practice are to be expected. In considering the curriculum she notes that the nursing of puerperal women is often less efficient than it should be; in such concentrated training it is easy to neglect the unsensational routine of maternity nursing apart from actual delivery. Antenatal work has also been dealt with too lightly in the past; comparatively few midwives now in practice have had any useful training in this respect, and probably for this reason fail to make full use of the maternity welfare clinics. The feeding, care, nursing, and management of premature or diseased infants are special branches of her profession of which the midwife should also have practical experience. Unfortunately the colleague responsible for her training is not always really qualified to impart such complete equipment. To provide against this possibility, Dr. Campbell suggests the institution of a special certificate for teachers, not necessarily to eliminate the approval of practical midwives in this capacity, but to ensure that a teacher shall have the necessary degree of personal education and a knowledge of more recent developments of midwifery, as well as facilities and equipment for undertaking a 12 months' course of training. The majority of practising midwives, though competent and successful in their work, have not these qualifications; their teaching is still further limited by the possible susceptibilities of their patients, and they cannot afford to risk damaging their own practices by such methods as, for example, systematic antenatal supervision, which might annoy or alienate the women attended. The certificate for teachers would not imply any overstepping of the legitimate functions of a midwife and would, we consider, be an excellent step. Of more doubtful utility is Dr. Campbell's suggestion to register and thus recognise "handy-women." She does not propose that any qualification should be required for registration, but merely that suitable women engaged in maternity nursing should be accepted. Any unregistered woman found undertaking this work would then be liable to prosecution. The only requirements upon which it would be possible to insist in all cases are good character, personal cleanliness and physical fitness, temporary or permanent suspension from the register following proved unfitness in any of these respects. Dr. Campbell does not believe that registration would enhance the status of the handy-woman, but that the inconvenience of being subject to suspension by, say, the inspector of midwives, would act as a discouraging factor on her employment. We have some qualms, however, about her hopeful suggestion that difficulties would not arise over the inspection of unqualified women working directly under a doctor; nor do we anticipate that those fully trained monthly nurses who are not midwives would appreciate being enrolled in the same list as quite untrained women. It is not easy to see how best to relegate the handy-woman to her proper function of home-helper, but though the advantages of registration, as outlined by Dr. Campbell, are not inconsiderable, we do not think this proposal will meet with general approval. A section on the midwife and the public health service concludes an admirable report.

---

[1] Deutsche medizinische Wochenschrift, June 29th, 1923.

Dr. Andrew Balfour resigns on Oct. 31st his post as Director-in-Chief of the Wellcome Bureau of Scientific Research to take up other important duties. He will be succeeded by Dr. C. M. Wenyon, who for the past nine years has been Director of Tropical Research at the Bureau.

WE regret to announce the death, on Sept. 8th, of Mr. Gustavus Hartridge, ophthalmic surgeon to Westminster Hospital, and gratefully known to many generations of students for a lucid manual on the refraction of the eye.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XXXVI.

MENORRHAGIA IN YOUNG WOMEN WITHOUT GROSS LESION.

THE menstrual function is governed by internal metabolic changes of which hæmorrhage from the endometrium is but the outward and visible sign. The unseen and little understood metabolic processes naturally tend to be overlooked and the uterus, particularly its mucous lining, regarded as the organ at fault in menstrual disorder. It is curious that while amenorrhœa and scanty menstruation are accepted as due rather to general bodily states, such as malnutrition, anæmia, &c., excessive or painful menstruation is usually ascribed to deviation in the position of the uterus or disease in the endometrium, so that alteration of position and curetting have had an undue prominence in treatment.

It is essential in the first place to make sure of the precise nature of the trouble. Patients often seek advice because their normal habit is in excess of the average and, though perfectly well, think the loss is greater than it should be. Such patients require no treatment; it should be explained to them that their type is natural to them, although above the average in quantity or duration. On the other hand, definite change in the menstrual habit in the direction of excess is an indication of disturbance whether it causes symptoms or not, and the general health and circumstances of the patient call for investigation. If the menorrhagia is a symptom of organic disease, renal, cardio-vascular, or suchlike, the treatment will be that of the primary condition, but the vast majority of cases do not exhibit serious organic disease, and the most common provoking factors are those of a nervous and psychical origin or a change in the mode of life or occupation, as, for example, from a healthy outdoor life in the country to a sedentary occupation in town. Here treatment must consist chiefly in advice on how best to order the patient's present mode of life so as to remove the causes predisposing to her trouble. Unless this can be done no medicinal or other treatment will avail. The shop assistant or waitress on her feet all day in a stuffy atmosphere may obtain some benefit from physical exercise at her off times, if not too tired to enjoy it, from regulation of the bowels and other general hygienic measures, but unless she can continue at work through her periods she will not be able to keep her place. If the menorrhagia persists she must, at any rate for a time, give up work, when probably her natural habit will soon return. Ergot, calcium lactate, and the cotarnine salts are disappointing; generally the most valuable drugs are the bromides, but they are rarely successful unless the patient can rest at the time of the period. Improvement of the physical condition is essential, and the best possible use must be made of the intermenstrual period. The cases that respond most readily to hygienic treatment are those with excessive loss with normal intervals; the troublesome cases are those with shortened clear intervals.

Though less serious in its effects, the type in which a slight discharge—often termed "draining" or "dregs" by the patient—persists after the free loss has ceased is particularly difficult to treat; it is common in nervous women and causes them much mental distress. The continuance of a slight discharge should not be allowed to interfere with outdoor pursuits, and if once the patient can be persuaded to concentrate on her physical condition and not on her ailment, the likelihood of her recovery will be greatly increased. Curetting is rarely of use, but may be tried in those over the age of 25, in whom other measures have failed; the possibility of an intra-uterine polypus or general endometrial hyperplasia makes one curetting worth while, but the factor producing the endometrial overgrowth, if not removed, will sooner or later cause a return of the condition. However, inasmuch as curetting affords an excuse for rest in bed, followed by a holiday, it may be the means of giving the patient a fresh start. Probably a judicious use of this time will do more than the operation itself.

The Endocrine Glands and Menstruation.

In spite of the extensive literature on organotherapy in menstrual disorders, our knowledge of endocrinology is as yet too fragmentary to admit of a rational basis for therapeutics; what is attempted is either empirical or speculative. Dr. H. Gardiner-Hill is now undertaking at St. Thomas's Hospital a study of the menstrual function in gross disorders of certain endocrine glands in the hope that it may lead to recognition of an endocrine factor in the less obvious cases. Apart from the ovaries, where abnormalities of function are difficult to assess, the endocrine glands chiefly associated with menstrual disorder are the thyroid and pituitary. Divergent views still exist as to the nature of this relationship and even as to the type of menstrual derangement likely to occur in gross disorders of these glands. The uncertainty arises partly from the difficulty of excluding abnormalities of other endocrine glands. The disordered menstruation accompanying gross disorders of the thyroid and pituitary glands may, indeed, be independent of a specific action of the hormones concerned, since profound alterations in the general metabolism are also produced. Both menorrhagia and amenorrhœa have been described as accompanying both hyper- and hypo-thyroidism. The general opinion seems to be that, while the majority of cases of Graves's disease show a tendency to diminished menstruation or amenorrhœa, if any irregularity at all is present, the majority of cases of hypothyroidism show a tendency to menorrhagia. The stage at which the condition arises, however, may be a factor of importance. The absence of the thyroid hormone in the cretin is generally held to be responsible for lack of development of the genitalia, and consequent amenorrhœa; if treated, however, the cretin appears to commence menstruation about the average age. Minor degrees of hypothyroidism, especially if the onset is in early adolescence, seem to give rise to early menstruation and a tendency to menorrhagia; at the onset of myxœdema in adults the menstrual tendency seems also to be in the direction of excess rather than deficiency. On the other hand, amenorrhœa is often stated to accompany myxœdema, possibly because myxœdema frequently arises at the time of the menopause, artificial or natural. An important relation undoubtedly exists between the pituitary gland and ovarian function, but how far pituitary disturbance can be a cause of menorrhagia is little known, except that in the early stages of acromegaly with anterior lobe hyperplasia overgrowth of the genitalia with menorrhagia occurs and is soon followed by the opposite phase of decreased sexuality and amenorrhœa.

In gross disturbance of the thyroid or pituitary gland menorrhagia is not usually the most prominent symptom. When, however, menorrhagia is a major symptom and gross thyroid or pituitary derangement not obvious, the possibility of some minor endocrine disturbance should be borne in mind, notably in cases occurring at the physiological epochs, such as puberty, after childbirth, or the menopause, especially if any toxic condition is superadded. If signs of endocrine disturbance are noted, an estimation of the basal metabolic rate provides a valuable indication of the existing state of function of the thyroid gland.

Abnormal conditions of the pituitary gland will usually be accompanied by disturbance of growth and metabolism. The patient's height and weight should be compared with the average normal for her age. Radiographs of the sella turcica should also be taken in doubtful cases, while estimations of sugar tolerance may provide additional evidence of pituitary disturbance.

Organotherapy.

The above factors must all be taken into consideration when considering the likelihood of success of organotherapeutic measures in menorrhagia. Up to the present three organic extracts have been chiefly used with varying results. These are thyroid extract, pituitary extract, and extracts of the corpus luteum. The empirical treatment of excessive, scanty, or absent menstruation by thyroid extract is sometimes followed by the return of normal menstruation, and at the climacteric by diminution of the general disturbances associated with this period of life. Thyroid extract is, however, a powerful stimulant to metabolism in general, and possibly these results are due to a general improvement in nutrition. Basal metabolism estimations would appear to provide the best guide as to the need for, and dosage of, thyroid extract in these cases. It should be tried in small doses, ¼ to ½ gr. at night to start with, and gradually increased as the indications arise. As to pituitary extract, the general opinion seems to be that results are disappointing, and when successful may be due to the well-known local action of pituitary extract on the uterine muscle. The recent work of W. E. Dixon suggests the likelihood of menorrhagia occurring with hyperactivity of the pituitary, and pituitary extracts have been recorded as producing good results in cases where ovarian function is deficient. Extracts of corpus luteum have also been used, chiefly by American observers, on the supposition that one function of the corpus luteum is the checking of the menstrual flow. Good results have occasionally been obtained, but apparently in menorrhagia during later, rather than earlier, menstrual life. Our knowledge of the properties of extracts of corpus luteum, however, is as yet meagre, and their administration is, to say the least, speculative.

Conclusion.

The treatment of these difficult cases may be summed up thus. Reliance must be placed chiefly on general and hygienic management of the patient, especially in regard to removing unfavourable conditions in her life and occupation and promoting good physique; curetting is of little use as a therapeutic measure, and more often required for diagnosis in patients after the age of 25–30 than in younger women. Drugs are rarely of use, except perhaps sedatives when there is nervous and psychical disturbance. The organic extracts are occasionally of use, but further investigation will be necessary before a scientific basis is obtained for their administration.

MEDICAL EXAMINATION OF DRUNKEN MOTOR DRIVERS.

WORKING OF THE NEW LAW IN DENMARK.

No one denies that the drunken motor driver is a dangerous nuisance. But to deal with him in a manner that is both effective and fair to all concerned is no easy matter. To fine him or lock him up for a month is often merely to temporise and put off the evil day—the second occasion when his tendency to get drunk may mean the death of one or more of his fellow beings. In this country we seem to be moving towards the rule that the motorist once convicted of drunkenness while driving must lose his licence for ever. This rule has already become law in Denmark, the law of 1918 having been revised in 1921 in such a way that, according to paragraph 34, the motorist convicted of drunkenness while driving may have his licence permanently withdrawn. Paragraphs 32 and 34 of this law of 1921 refer to two degrees of alcohol poisoning—"drunkenness" and "being under the influence of alcohol." As there is, of course, no hard-and-fast line between severe and slight intoxication, it soon became evident to the police in Denmark that, if the new law was to be administered justly and effectively, certain standards and criteria would have to be formulated, and soon after the law came into force they solicited the aid of the Danish Medico-Legal Council. An account of the correspondence which followed and of the practical outcome thereof has recently been given by Dr. J. Fog in *Ugeskrift for Laeger* for August 23rd.

In his letter to the Medico-Legal Council, the chief of police pointed out that the decision whether a motorist is drunk or sober has become a most serious matter since, in the former event, the motorist's career may be permanently terminated. It was therefore felt by the police that in cases of alleged drunkenness in drivers, a medical examination is essential. But the police felt it incumbent on them to point out that examinations for drunkenness by medical men had not been carried out in the past on a uniform system, nor had the wording of the reports of such examinations been invariably clear. Hence the difficulties which the police and legal authorities had had in acting on the reports of medical examiners. It was therefore hoped that the Medico-Legal Council would help to clear up this state of affairs and assist the police in choosing a medical expert who would be at the service of the police day and night. In answer to this appeal from the police, the Medico-Legal Council engaged the services of an alienist, Prof. A. Wimmer, and of a pharmacologist, Prof. J. C. Bock, to help work out a detailed scheme to be followed by a medical examiner called on to investigate an alleged case of drunkenness. In the reply of the Medico-Legal Council to the chief of police, it was pointed out that while definite tests could be devised for distinguishing between drunkenness and complete sobriety, the detection of the slighter degrees of alcohol poisoning was a matter of great difficulty. The Council's proposed tests referred therefore only to the diagnosis of definite drunkenness. These tests, it was pointed out, may be classed under three headings: (1) Chemical examination of the blood and urine; (2) psycho-physical examinations; (3) an ordinary clinical examination. In the case of the arrested motor driver, the Council came to the conclusion that only a clinical examination is necessary in practice, and the following programme was devised as a guide to the examining police surgeon, the scheme being sufficiently detailed for any doctor to carry out the examination to the satisfaction of the authorities.

1. Observe the driver's appearance. Drowsiness, drooping eyelids, relaxed features, congestion of the face and conjunctivæ, sweating, slobbering, disordered dress, and the like should be noticed.
2. Observe his behaviour. Noisiness, silly behaviour, excitation, garrulity, restlessness and other characteristics should be noticed.
3. Is his sense of time and space natural? If it is, say "Yes," if not, repeat his statements.
4. Test his memory. Note if he can remember a couple of addresses, and test his ability to describe something—i.e., how the motor accident happened, or the meaning of a drawing in an illustrated paper.
5. Note his speech: is it thick, nasal, lisping, or stammering? Let him repeat difficult words or read aloud a short notice in a paper.
6. Note his gait. Swaying and ataxia should be noticed, and Romberg's test should be carried out.
7. Test the movements of his hands and also his handwriting, telling him to write his name, age, station in life, and address on a sheet of paper.
8. Note if his pulse is regular and rapid, the condition of his pupils, and his response to painful stimuli.
9. Note if he smells of alcohol.
10. Are there signs of other diseases such as epilepsy and apoplexy?

Dr. Fog was charged with the task of putting this scheme into practice, and he has already examined 50 alleged cases of alcohol poisoning in motor drivers. The account he gives of these examinations shows what an elaborate process the Medico-Legal Council has devised. The average duration of a single examination is about 45 minutes. The medical examiner loses no time lest the condition in which he finds the driver should have changed since his arrest. The interview between the driver and the medical examiner is, as a rule, conducted in the absence of a third person, and the examiner hastens to assure the driver that he, the examiner, is a neutral, unbiased party, anxious only to find out the truth. In the quiet atmosphere of this tête-à-tête meeting, the driver, whose excitation is solely due to an accident and the events following it, soon settles down and carries out the various tests satisfactorily. On the other hand, the drunken driver who has been temporarily sobered by the shock of an accident and the prospect of losing his licence for ever, may at first pull himself together to pass certain tests. But the maintenance of such artificial sobriety for the better part of an hour is an almost impossible task, and if he is really drunk, the driver sooner or later betrays himself.

With regard to the value of the tests devised by the Medico-Legal Council, Dr. Fog has found that the fourth test is very delicate; none of the drivers classified as drunk, and hardly any classified as suffering from slight alcohol poisoning, could pass this test satisfactorily. But the fifth test, which also included sums in arithmetic, was of less value. Two drivers, who were found to be sober, could not pass simple arithmetical tests. Handwriting tests proved of little value, for the handwriting of comparatively uneducated men may be bad, however sober they are. As for the pulse-rate, it was of practically no value. Indeed, the average pulse-rate of the drivers discharged as sober was a little higher than that of the drivers declared drunk or suffering from slight alcohol poisoning. Test 9 was of value only when negative; merely to smell of alcohol is of little diagnostic value. All the three drivers not smelling of alcohol were discharged as sober.

Dr. Fog's classification of his 50 cases brings out some interesting points. All the drivers were men, and the age of 41 of them was between 20 and 39. There were 34 professional chauffeurs, and 16 amateur or private drivers. In as many as 34 cases an examination was required between 8 P.M. and 8 A.M., and in 19 of these cases an examination was required between midnight and 6 A.M. Only 9 of the 50 drivers were discharged as sober. Of the remainder, 11 were classified as drunk, and 30 as suffering from slight alcohol poisoning. It is evident from this interesting paper that, under conditions obtaining in Denmark, the medical examination of a motor driver accused of drunkenness is so elaborate and systematically carried out that there is little chance of a miscarriage of justice.

WHAT DOES THE PUBLIC HEALTH SERVICE DO FOR ME?

DISSEMINATION OF HEALTH INFORMATION IN U.S.A.

THE Federal Public Health Service of the United States of America has issued a series of leaflets intended to be read by the older scholars in upper grade and high schools. It has been prepared to meet the general demand for information in regard to the health work now being done by both National and State authorities. The discussion is in six parts, three being subdivided into two sections each, their average length being about 650 words each. The first part is introductory and its purport may be gathered from the extract below. In the second part we are told what the public health service does for the young, and the work of vaccination, of child welfare organisations, of school examinations, and the like, is described. In the third part precautionary measures in regard to travel are noted; in the fourth part we are informed how the public health service protects from communicable diseases. The fifth part deals with the solution of interstate health problems, including paragraphs on standardisation of special products. In the sixth part some portions of industrial hygiene are emphasised. The following extracts will serve to indicate the scope of the whole.

On the Dissemination of Knowledge.

Dissemination of health information is enormously important. Other countries, of course, disseminate it; but they do it chiefly for professional men, doctors, bacteriologists, and not until recently for the benefit of the "man of the street." The U.S. Public Health Service, on the other hand, addresses all the people. Some very technical publications are especially for the benefit of scientists, but by far the greater part of its publications deal with subjects that interest the everyday man, and with some that interest the everyday youth.

It disseminates information concerning new investigations, new discoveries, and new methods, by means of printed books, newspaper articles, radio broadcasts, public lectures, demonstrations, and school-children. Dissemination by children is very important; for when children learn a thing they can be relied upon to educate their parents.

The task of State health authorities, on the other hand, is to collect vital statistics (records of births, deaths, diseases, &c.); to prevent disease by vaccination, inoculation, and house quarantine of the sick; to supervise drinking water, milk, food, sewers, street sanitation, school sanitation, &c.; to inspect factories, workshops, &c.; and in some States to provide school nurses and school physicians.

Broadly spreading, the U.S. Public Health Service finds out things and the State and local health authorities apply them; though, of course, the State and local organisations find out a good many things and the Public Health Service applies a good many. Whichever way they work, however, they work together and get the maximum efficiency.

Foreign Quarantine.

Most important of the direct work for protection against disease is that of barring foreign diseases from our shores. This was almost the first duty undertaken by the Public Health Service, which was organised 125 years ago under the name of the Marine Hospital Service and charged with the medical and surgical care of merchant seamen. Owing to this duty it was usually the first to discover any disease brought from abroad. From this the Quarantine Service of the U.S. Public Health Service developed.

The States, of course, had control of their ports and at irst most of them established their own quarantines. Later, however, it became evident that the National Government was best fitted for carrying out such work; and one after another the States turned over their stations to the Public Health Service. New York, the last, fell in line about two years ago.

Some years ago the quarantine work of the Service was divided into two parts—foreign and domestic. Foreign quarantine has to do with diseases coming from abroad and domestic quarantine with the spread of disease among the States.

The Public Health Service has two lines of defence against foreign diseases, one abroad and the other at home. n all, 77 officers man the first line, 31 in Europe, 2 in South America, 7 in Mexico, 3 in China, 19 in the Philippines and Hawaii, and 15 in Cuba, Porto Rico, the Virgin Islands, and Panama. These officers are stationed at as many sea ports, where they are charged with preventing the sailing for America of emigrants infected with diseases, especially with typhus, cholera, plague, and yellow fever.

In Europe the task has of late years not been easy. The would-be emigrants were mad to get to the United States; and their native countries were for the most part glad to have them go; and some of the steamships were not averse to carrying them, but were averse to spending money for delousing plants, &c. The Public Health Service could not directly compel them to do this, nor could it everywhere do it itself, for some European countries objected on the ground that in setting up the necessary facilities the United States was encroaching on their sovereignity.

The Public Health Service had to counter by requesting the State Department to instruct its consuls in Europe to refuse a bill of health to vessels sailing for the United States with passengers who had not been subjected to cleansing measures and by instructing its own quarantine officers to delouse immigrants on arrival in this country and to detain them, in case of suspicion, for 12 days thereafter. Only by this action were some steamship companies induced to instal disinfecting plants abroad. Aided by the present restrictive immigration law and by the disinfecting and delousing facilities, conditions are now reasonably satisfactory. The restrictive law is, however, until July 1st, 1924, only, and unless it is renewed or in some way replaced the tidal wave of immigrants waiting in Europe for the letting down of the bars will rush for this country at the first opportunity and the resulting pressure will test every timber in the health barricade.

Leprosy.

According to the best estimates there are now in the United States 500 to 1500 lepers, a mere bagatelle compared with those suffering from tuberculosis, which is for that matter far more contagious and far more deadly. Nevertheless, knowledge of the presence of a leper in a street car, for instance, would cause a panic and that of a tuberculous patient could cause scarcely a thrill.

Public opinion has insisted that the Federal Government shall take charge of all lepers, and it has undertaken to do so.

In 1917 Congress provided for a national home for lepers to be administered by the Public Health Service, but so strongly did the various States object to its location within their borders that it was not until four years later that the Service was able to acquire a leper home (in Louisiana). This home is still being enlarged, and each new ward is rapidly filled. The Public Health Service, on application from a proper State authority may accept as a patient at this home any leper found in any State, with the exception of aliens subject to deportation from the country. This protects you in steadily increasing measure against possible contact with lepers who are at large.

Leprosy has been found in a measure amenable to treatment. Nearly one-third of the patients at stations in Hawaii have been released as being no longer a menace to public health, and of these only about one-eighth have relapsed.

Examination of Biological Products.

Some years ago Congress assigned to the Treasury Department operating through Hygienic Laboratory of the Public Health Service the duty of making tests of "biological products" and of inspecting the factories where these "products" were manufactured. No bacteriological product may be shipped in interstate commerce not bearing the indorsement of the Laboratory. This indorsement is, of course, not as to the medicinal value of the product but is merely as to its strength, toxic properties, and the sanitary conditions under which it is manufactured.

Most States have officially adopted the Public Health Service standards; but some still allow the manufacture within their border of products whose manufacturers are unwilling to submit them for testing or their factories for inspection. Such products may not be shipped from State to State.

The Public Health Service has standardised products for use against diphtheria, lockjaw, dysentery, meningitis, pneumonia, and typhoid.

Within the last 20 years the death-rate from diseases now treated by bacteriological products has been enormously reduced. Small-pox, except where vaccination has been neglected, has been almost abolished; meningitis to about one-sixth and diphtheria to less than one-third; rabies, if taken in time, can almost always be prevented; tetanus has been greatly reduced.

Medical Departments in Industrial Plants.

The establishment of medical departments in most of the industrial plants of the country was also in part due to the Public Health Service. Such departments attend not only to employees who are injured in accidents or who are taken sick at the plant, but they also investigate the causes of any disease that breaks out in the plant and eradicates it, thereby making the factory more healthful and reducing absenteeism and the cost of finding new men to replace those who quit. They keep records, too, from which the Public Health Service may work out, as soon as enough are available, a health standard based on the normal or average amount of absence from work on account of sickness. Such a standard is expected to bring about important improvements in factories that find themselves below par.

The effect on the physique and health of industrial workers, especially women, resulting from the monotonous and rapid repetition hour after hour and month after month of movements in themselves light and simple, is now being investigated.

The Public Health Service is of opinion that, so far, though conclusive proof is lacking, it is probable that serious injury may be caused by any work, the performance of which calls for cramped, constrained, or awkward posture. Less certain is the effect of such work on the nervous system. That the constant repetition of a movement does in time affect this system is more than probable, but how importantly it affects it has not been established. This investigation will almost certainly result in great benefits to working women.

VITAL STATISTICS FOR 1921.

THE REGISTRAR-GENERAL'S REVIEW.

The text of this Review,[1] being one of three volumes comprising the entire survey, is now published one year and eight months after the termination of the year to which it relates, and many months after the publication of the tables which are necessary for complete study of the present volume. It contains the valuable, chiefly medical, commentary on the vital statistics for the year 1921.

A Phenomenally Low Death-rate.—As in the previous year (1920) there was experienced also in 1921 a lower death-rate than in any previous year since 1837, the main explanation of this being a succession of two exceptionally mild winters. Had the death-rate for 1921 been stated in terms of the standard population recommended by the International Statistical Institute it would have been 12·5 instead of 11·5 per 1000.

Comparison of the Two Sexes.—Much interest attaches to the relative mortality of the two sexes at various periods of life for equal numbers living. Reference to Table III. in another volume shows, as pointed out in this report, that prior to 1920 in no year was the death-rate at ages 85 and upwards higher in females than in males, as it was in 1921 (in the proportion of 100 to 95). At ages under 5 in the same year the male death-rate was 25 per cent., at ages 5–10 it was 3 per cent., at ages 15–45 it was 16 per cent., at ages 55–65 30 per cent., at ages 65–75 21 per cent., and at ages 75–85 14 per cent. higher in males than in females. There remains the age-period 10–15, in which male mortality was 3 per cent. lower than that of females, a phenomenon which, with few exceptions, has held good for many years.

Infant Mortality was at the rate of 83 per 1000 births, lower than in any previous year except 1920, when the deaths numbered only 80 per 1000 births. The hot dry summer of 1921 might have been expected to cause a large excess of diarrhœal diseases, but the amount of these diseases was well below the average of all years preceding 1915, though higher than in the more recent years preceding 1921. The valuable tables given on pages 6 and 7 of this Review are worthy of detailed study by all hygienists. They show, inter alia, the error of the commonly accepted statement that the death-rate in the first four weeks after birth has not declined. It was 40·6 in 1911 and 35·2 in 1921, and the variations in different localities were much greater than are indicated by these average rates for the whole country. In the next two months of infancy the death-rate between 1911 and 1921 declined from 24·7 to 14·7, in the third to the sixth month from 25·9 to 13·7, in the next three months from 20·6 to 9·7, and at 9–12 months from 17·4 to 7·8. In another table is shown the influence of urban life on infant mortality. In the first four weeks urban excess over rural was 7 per cent., in the next two months it was 25 per cent., in the third to the sixth month 49 per cent., and in the two next three-monthly periods 44 and 48 per cent. respectively.

The *Regional Distribution of Infant Mortality* has great importance. In the north of England as a whole it was 38 per cent. higher than in the south, an excess which is greater than the excess of infant mortality in county boroughs over that in aggregate rural districts. It is marked even in the first day after live birth (20 per cent.), and it amounts to 34 per cent. in the first four weeks after birth, and there is therefore opened up here a region for investigation by medical officers of health which should bear fruit, especially in improved care of mothers before, during, and after childbirth.

Deaths from Suffocation.—Up to the year 1914 accidental mechanical suffocation had varied little during 30 years. It declined rapidly in 1915 and 1916, and since then has fallen from 1·40 per 1000 births in 1914 to 0·59 in 1921. (To see the progress of events year by year it is necessary to refer to another volume.) Furthermore, while in past years mortality from this cause was much greater in the south than in the north, and especially excessive in London, the decreased mortality is not very unequal in all parts of the country. It is difficult, as is said in the report, to dissociate this change entirely from the war, and the decreased consumption of alcohol at once suggests itself as a possible explanation; though it appears not unlikely that some change may have taken place in the attitude of coroners to suspected cases investigated by them.

Increase of Excess Mortality of Male Infants.—As is well known, male infant mortality is always higher than female. Owing to the fact that comparing, for instance, 1881–90 with 1921 the male infant death-rate has declined only 45, while that for females has declined 48 per cent., the difference between the two sexes is slowly increasing. The excess in the mortality of males is greatest in the earlier months of infancy, and as the recent fall in infant mortality has occurred chiefly in the later months, this in itself explains some of the increased difference between the mortality in the two sexes. In this connexion it is necessary to think of early infant mortality as partly avoidable and partly inevitable, and if it be assumed, as is not unlikely, that a larger proportion of male than of female infantile deaths are in the latter category, it follows that reduction of infant mortality must be associated with an increased difference between male and female infant mortality. A comparison of the cause of events in other countries shows no movement in the opposite direction, although in only a few of the countries whose experience is quoted in the Review is there as large an increase in male excess as in this country.

(*To be continued.*)

Royal Institute of Public Health.—A course of lectures on Problems of Personal and Public Health will be delivered in the Lecture Hall of the Institute, 37, Russell-square, London, W.C., at 4 P.M. on Wednesdays, beginning on Oct. 17th. Among the lecturers will be Dr. Alfred Greenwood, Prof. J. C. Drummond, Major H. Graeme Anderson, Dr. W. A. Bullough, Mr. William B. Smith Dr. C. W. Saleeby, Dr. Kate Platt, Dr. A. H. Bygott, and Mr. H. D. Herring.

The Harben Lectures will be given by Prof. C. Levaditi, M.D., of the Pasteur Institute, Paris, on Dec. 11th, 12th, and 13th on: (*a*) Neurotropic Virus (Encephalitis); (*b*) Neuro-vaccine; (*c*) New Discoveries in the Treatment and Prophylaxis of Syphilis.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Health of Belfast.

THE report of Dr. H. W. Bailie, medical superintendent officer of health for the year 1922, has just been issued. The general improvement in the health of the city is shown by the fact that the total number of deaths in 1922, viz. 6304, with a population of 425,000, is less than the number, viz. 6910, in the year 1892, with a population of 261,046, the respective rates being 14·8 per 1000 and 26·5 per 1000. The rate for 1922 shows a fractional increase over the previous year—14·8 compared with 14·4 per 1000. Typhoid fever, which was formerly very prevalent, has almost disappeared. The number of cases was 75 with 7 deaths, a mortality of 9·3 per cent. No case of typhus fever occurred during the year. Scarlet fever was prevalent but in a very mild form. There were 741 cases with 12 deaths, a mortality of 1·6 per cent. Diphtheria was also prevalent. There were 497 cases with 43 deaths, a case mortality of 8·65 per cent. Measles caused 33 deaths, equivalent to a death-rate of 0·08 per 1000 of the population. Whooping-cough caused 16 deaths, equivalent to a death-rate of 0·04 per 1000 of the population. Diarrhœa caused 152 deaths, equivalent to a death-rate of 0·36 of the population; of the total number 127 were children under 2 years of age, and 25 were 2 years of age and upwards. There were 8 cases of cerebro-spinal fever with 3 deaths. Influenza caused 241 deaths. Phthisis caused 624 deaths, a rate of 1·5 per 1000. Pneumonia caused 594 deaths, a rate of 1·4 per 1000. Cancer caused 363 deaths, a rate of 0·9 per 1000. There was a reduction of 0·8 per 1000 in the death-rate from zymotic diseases, and an increase of 0·4 per 1000 from chest affections compared with the previous year. The birth-rate was 25·1, a decrease of 1·2 compared with the previous year. Infant mortality was 94 per 1000, or 21 per 1000 less than the previous year. The natural increase of the population was 4363. At the out-patient clinics for venereal disease 2376 cases were treated, and 420 patients received treatment as in-patients. The total cost of treatment of persons suffering from venereal diseases was £6544 5*s*. 8*d*., of which 75 per cent. of the cost incurred was recouped to the corporation. The number of houses disinfected during the year was 1882. Five maternity and child welfare centres were in operation. The number of names upon the rolls was 24,287. Of 16,503 cows slaughtered during the year 35, or 0·21 per cent., exhibited lesions of disease in the udder; 12·33 per cent. of cows were found to be tuberculous.

Belfast District Asylum.

Dr. N. B. Graham's report for the year 1922 shows that the number of patients was 975, males 466, females 509. Discharged patients numbered 141, of whom 78 were cured. There were 74 deaths. Of these, 17·5 per cent. were due to general paralysis of the insane, 16·2 to phthisis, 14·8 to cerebral softening. As regards causation, the most potent factor was found to be a faulty heredity, the other chief causes being mental stress, critical periods, and syphilis. In only 2·6 per cent. of the admissions was alcoholic excess considered to be the principal cause of the insanity, but in 10·9 per cent. it was believed to be a contributory cause. A large increase in the accommodation for patients is in progress. Dr. Graham complains of the present state of the Lunacy Laws.

> "It is illegal to receive as 'voluntary' boarders early uncertifiable mentally afflicted patients, also certifiable harmless patients, who are willing to submit to such treatment, without certification. If the Lunacy Laws were amended to meet such conditions, the stigmata of certification, so much dreaded by patients and their relatives, would be removed; they would, therefore, be advised and encouraged to submit to such treatment, and so facilitate early recovery."

The Government of Northern Ireland may be expected shortly to deal with this important matter. It is a feature of the asylum, which is situated in a spacious park some miles from the city, to encourage work amongst the patients. About 60 per cent. of the patients are regularly employed, many of them in agricultural work, and this is found to be very beneficial. The asylum is on the villa system which has proved most satisfactory.

Tuberculosis in Belfast.

The annual report of Dr. A. Trimble, chief tuberculosis officer, shows that the death-rate from pulmonary tuberculosis for the year 1922 was 1·5 per 1000. This represents a reduction of 45 per cent. as compared with the year 1918, and a reduction of 68 per cent. as compared with the year 1890. A similar fall occurred in the death-rate from non-pulmonary forms of tuberculosis. The influence of housing is shown by the fact that in 62 per cent. of the new cases examined the conditions were reported as under average. The analysis of occupations shows the relatively large number of cases occurring in clerks, engineers, spinners, stitchers, reelers, winders, doffers, labourers. Discharged soldiers showed a high proportion. It is noteworthy in view of the staple trade of Belfast that flax-dressers and other branches of the trade showed a moderate ratio amongst males and a rather high ratio amongst females. The female rate in general continues to show a considerable excess over the male rate. In 42 per cent. of cases the patients were found to have had personal association with infected persons. The rate amongst new patients varied in the different wards of the city from 5·6 per 1000 of the population to 1·5 per 1000. The proportion of pulmonary, as compared with non-pulmonary cases, was 75 to 25. The open-air school for children living in contact with tuberculous cases has been attended with great success. Sanatorium, dispensary, and domiciliary treatment is pursued.

Public Health Services.

MENTAL HOSPITALS SERVICE.

NINE recently published reports of county and borough asylums[1] offer examples of certain changes which are slowly becoming general. The removal of adverse conditions produced by the war is evidenced by an improved state of general health in the patients and lower death-rates—in particular, deaths from tuberculosis and the numbers of active cases of this disease are both fortunately diminishing. Dysentery also appears to be less common, and several outbreaks of enteric fever recorded appear to have been traced promptly to their source and kept within very narrow limits. The improvement in the patients' health is attributable in part to a more liberal diet. Dinner appears to be a universally satisfactory meal, but the all too familiar and oft-repeated suggestion in the commissioner's report that breakfast and tea should be made less monotonous is still to be found in most of these publications.

Another change, exhibited in greatly varying degree, is a response to the demand for efficient medical treatment in cases of insanity. Visiting dentists are now almost universal, although in some cases their hours of attendance can only allow of treating the most flagrant cases of dental sepsis among the patients. Surgeons and other consultants have been appointed in some cases, and at Hill End (Hertfordshire) an operating theatre has been built, and at Nottingham a pathological laboratory.

The constitution of mental hospital staffs is not apparently sharing in the general trend of progress towards greater efficiency. The junior posts in this service remain ill-paid, and open only to bachelors, and the proportion of physicians to patients remains in many cases undesirably low. At Barming Heath (Kent), for example, the post of second assistant medical officer is again vacant, as recorded in last year's report. At Chichester the post of third assistant medical officer is not only vacant, but intended by the committee to remain so indefinitely, one result of which, as pointed out by the commissioner, is that bacteriological and other laboratory work is at a complete standstill, and a well-equipped laboratory is unused. The most astonishing example of this policy (for it appears to represent an actual policy of staff reduction in some cases) is to be found at Carmarthen. Here the second assistant medical officer has had notice to terminate his services, and an institution containing nearly 600 patients is in future to be administered by the medical superintendent and one other medical officer. At the same time the number of nurses has been reduced, and their hours of service increased to 66 per week. To quote the commissioner's report :—

---

[1] Annual Reports of the Brighton County Borough Mental Hospital, of the Kent County Mental Hospitals, of the Hertfordshire County Mental Hospital, of the Nottingham City Asylum, of the Monmouthshire Asylum, of the Joint Counties Mental Hospital, Carmarthen, of the West Sussex County Mental Hospital, of the Asylums Committee, City of Birmingham, and of the Down District Lunatic Asylum, Downpatrick.

> "How all the work is to be efficiently carried out, not forgetting the lectures for the nursing staff, and due relaxation is to be afforded it is difficult to see. I trust the question will be reconsidered, and that the committee may feel their way to abandoning this step, as well as the reduction of the nursing staff by 14 (and that contrary as it appears to the advice of the medical superintendent) at a time when so much is being said as to the necessity for, if possible, more systematic and individal treatment in mental disease. As to the reduction of the nursing staff, I will only point out that during my inspection to-day I noticed one female ward, number 5, with 27 chronic, noisy, troublesome cases, with but one nurse, the result, I was informed, of the reduction which has already taken place."

The only reference to these remarks in the report of the committee of visitors is a formal record of the visit, the authors of which have the effrontery to declare that the commissioner "reported that all the patients appeared to be in receipt of due supervision and care." The purpose of this painful euphemism is difficult to discern.

Nottingham and Hertfordshire have given leave of absence on trial to a number of cases, in some of which money allowances were made. The neglect of this procedure receives comment in other reports, notably in that of Carmarthen, where apparently no patients whatever were given such leave.

Chichester records a wonderfully low death-rate, of only 2·38 per cent. A small outbreak of enteric fever evokes comment on the methods of handling foul linen, which apparently "differ somewhat on the male and female sides." An interesting after-comment on the Committee of Inquiry into the Administration of Public Mental Hospitals is to be found in a paragraph referring to a late patient at Chichester who gave evidence at that inquiry: "A letter has recently been received from the ex-patient himself, retracting his allegations and apologising for the statements, which, he says, were made owing to a morbid mental state." It is unfortunate that this letter cannot be given wider publicity.

The reports of the Downpatrick and Birmingham asylums are of unusual interest, both for the readable material and full information which they provide, and the former particularly for its numerous photographic illustrations. Great changes have taken place at Birmingham. Rubery Hill and Hollymoor, until recently leased by the Ministry of Pensions, have been taken over again, and "no less than 810 patients have been transferred from institutions situated outside the city as far apart as York and Hampshire without accident." Great improvements have been made in the buildings, and their equipment now includes clinical laboratories, examination rooms, operating and dental room, hydrotherapeutic room, and research laboratories. These were referred to in reporting the inaugural ceremony of the Joint Board of Research in Mental Disease. A bridge which will shortly be complete will unite the Rubery and Hollymoor estates, and "provide about three miles of varied exercise track, with rustic seats in certain wooded spots." Perhaps the most arresting feature of this report is an exhaustive analysis, on original and up-to-date lines, of the ætiological factors assigned in the 147 direct admissions of the year. These observations deserve wider publicity.

One or two of the reports under review yield practically no information whatever beyond what can be found in their statistical tables. It still appears to be incumbent on some medical superintendents to record the condition of crops and cattle, and repairs to boilers or drains. Admittedly the state of the fabric of an asylum, and every sort of function performed by everyone connected with it, have some bearing on the patients' welfare, and should be under the medical superintendent's control, but why he should be called upon to describe such activities as these rather than discuss the mental welfare of his patients in a report which in any case is usually all too brief is difficult to understand.

SCHOOL MEDICAL SERVICE.

Hertfordshire.

The number of children inspected was 13,509, and the percentage with defects 32·1. Enlarged tonsils accounted for 5·8 per cent., enlargement of submaxillary and cervical glands 3·8 per cent., and malnutrition 1·3 per cent. Schools were closed on 181 occasions compared with 46 closures in 1921, the increase being due to influenza, colds, and measles. The four orthopædic centres of the Herts branch of the British Red Cross Society which were organised by Mr. R. C. Elmslie, orthopædic consultant to the London County Council, have been in full working order for one year, and the results obtained have been very satisfactory. Dr. Hyslop Thompson reports that the centres have supplied a long-felt want in the county, and the improvement in many cases is very marked. The following are the cases dealt with :—

—	Males.			Females.		
	Under 5 years.	Under 14 years.	Over 14 years.	Under 5 years.	Under 14 years.	Over 14 years.
Paralysis	9	18	3	6	12	3
Bone defects ..	14	7	1	15	9	1
Spinal curvatures	0	9	1	0	15	8
Joints	0	2	1	3	0	4
Injuries	0	5	10	1	4	8
Miscellaneous ..	6	12	6	8	13	14
Totals	29	53	22	33	53	38
Both sexes ..	62	106	60	—	—	—

Norfolk.

During the year 13,698 children were examined in the routine groups. In addition, 2111 special inspections were made and 8427 children were re-examined. About 1 per cent. suffered from malnutrition, and Dr. J. T. C. Nash refers the decline in the number of these cases as being eloquent of the better conditions for farm labourers prevailing during the past few years, but is dubious of the improvement being maintained owing to the recent fall in wages. Cleanliness has improved with the exception of certain families which will always be "impossible." Refraction clinics were held at 97 centres and four dental vans equipped for inspection and treatment are employed by four dentists, 78 per cent. of the 18,270 children seen being referred for treatment, and about one-third of these taking advantage of the authority's scheme. There were 2305 school children excluded from school under Article 45(B) for infectious disease, 148 of these for influenza.

Forty-seven children received institutional treatment for definite or suspected tuberculosis, seven of these being of the non-pulmonary type. In addition 79 children were under domiciliary treatment. At the end of the year there were 28 cases still in institutions and 75 under domiciliary treatment. Dr. Nash is of opinion that, although sanatorium treatment is expensive, money is well spent in preventing the onset of definite clinical tuberculosis, and he considers that the nearer schools approach the open-air type the better, and suggests that less money might be spent on bricks and mortar and more on asphalted playgrounds, clothing, and food. "At the present time children, often poorly fed and inappropriately clothed, with defective footwear, have to sit for the best part of two hours in winter with cold, wet feet in rooms at a temperature under 50° F. in many schools. Is it to be wondered at that catarrh is common and that the children are too miserable to benefit fully from the instruction?"

One of the school dentists, Mr. Millican, contributes an interesting report on jaw deformities. He finds that children born and living on high sites or on the sea-front are freer from jaw or palatal deformity than children on low and damp sites, and he places the "locality" as the chief determining cause of jaw deformity.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdrs. R. H. St. B. E. Hughes to *Excellent*; F. G. H. R. Black to *Pembroke*, addl., for Chatham Dockyard, temp. Surg. Lt.-Comdrs. W. H. Sinclair-Loutit, R. Buddle, P. N. Button, W. J. Morris, J. F. Pace, J. F. M. Campbell, M. B. Macleod, and G. W. Woodhouse to *President*, addl., for five months' course of instruction at R.N. College, Greenwich. F. C. Wright to *Pembroke*, for Chatham Dockyard; and G. L. Ritchie to *Impregnable*. Surg.-Lt. R. W. Higgins to *Queen Elizabeth*.

ROYAL NAVAL VOLUNTEER RESERVE.

The following late Temp. Dental Surgs. have been transerred to the permanent list as Surg.-Lts.: T. P. Cooper, G. W. E. Holloway, A. G. D. Pridham, D. C. Lamond, E. G. Parkinson, G. R. D. Hankinson, and A. C. Bloomer.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Cols., late R.A.M.C., retire on ret. pay: J. B. Anderson, on account of ill-health contracted on active service; R. J. Blackham from half pay.

The undermentioned Capts. are seconded for service with he Egyptian Army: D. C. Bowie, J. C. Collins, and J. J. Magner.

Temp. Capt. N. Leonard relinquishes his commission and etains the rank of Capt.

TERRITORIAL ARMY.

Capts. W. M. Wilson and E. W. Herrington having ttained the age limit are retd. and retain the rank of Capt.

Lt. (Temp. Capt.) F. J. Cleminson relinquishes his commission and is granted the rank of Capt.

Capt. N. M. Fergusson to be Maj.

S. McC. Kirk to be Lt.

General Hospitals: Lt.-Col. Sir E. J. Maclean having ttained the age limit is retd. and retains the rank of Lt.-ol.

The undermentioned relinquish their commissions and etain their rank, except where otherwise stated: Majs. . C. Bevers and F. C. Pybus; Capts. H. M. Clarke, P. H. reen (granted the rank of Maj.), and J. A. Gunn.

Sanitary Companies: Capt. H. Duguid relinquishes his ommission and retains the rank of Capt.

INDIAN MEDICAL SERVICE.

Majs. E. C. Hodgson, W. Gillitt, C. H. Barber, W. Tarr, . Watts, I. D. Jones, W. T. Finlayson, W. T. McCowen, . E. Stanger-Leathes, J. M. Holmes, and M. F. White to e Lt.-Cols.

The King has approved the admission of the fol-wing: J. H. Barrett, G. H. Fraser, and T. H. Thomas be Capts.

Messrs. William Heinemann (Medical Books), Ltd. nnounce the early appearance of "High Blood Pressure: its ariations and Control," by Dr. J. F. Halls Dally; Pneumonia," by the late Dr. Robert Murray Leslie, edited, vised, and brought up to date by Dr. J. Browning exander; and "Manual of Practical X Ray Work," ird edition, by Dr. John Muir, B.Sc., in collaboration th Sir Archibald Douglas Reid.

BLOOD-DONORS.

To the Editor of THE LANCET.

SIR,—On the evening of Sept. 3rd a broadcast appeal for volunteers to act as blood-donors was sent out from King's College Hospital. The response was generous, the group-tests were done on the 4th, one suitable donor was selected, and the operation of transfusion arranged for the 5th. There the affair ends as far as the public is concerned. Expert criticism is disarmed by the statement that "the others have been classified for possible future emergencies."

One cannot help wondering how many of our hospitals find themselves in a similar state of unreadiness as regards blood-donors; nor can the reflection be avoided that in the majority this defect of organisation could be easily remedied. About six months ago, having need of a donor to give blood to a case of hæmatemesis (from gastric ulcer) I was fortunate enough to find at hand a known No. 4 volunteer; the transfusion was done at once, and the patient recovered. Realising that fortune is a fickle jade, I determined to make provision against a similar emergency, and to that end asked for volunteers amongst the employees of the Great Western Works, who number nearly 15,000, at Swindon. The response was generous; Dr. Knyvett Gordon came down and tested about 50 volunteers during one afternoon. At some convenient time in the near future another batch will be tested, but already, secure in the knowledge that at least a dozen No. 4 donors, of good physique and sound constitution are available at any moment, I have no anxiety now on this matter.

On two occasions since then I have been glad that this organisation existed, but the real criterion came on July 24th last when a man, aged 52, was struck by the flying fragment of a broken cutting tool in the left groin at the G.W.R. Works. Arterial blood cascaded from the deep wound inflicted. Two of his fellow workmen, trained in ambulance work, with commendable promptitude and efficiency controlled the femoral at the brim of the pelvis for 20 minutes, during which time, on an improvised operating table, and under ether, I was able to tie the external iliac artery. That being safely accomplished I enlarged the wound and tied the proximal and distal ends of the femoral and the severed profunda femoris. So far the account is not of special interest, and the replica could be furnished from hundreds of large works and hospitals. But as the last dressing was applied a workman approached me and asked, "Are you needing a No. 4 donor, because if you are, there is one ready waiting."

It is true that a large works offers ideal facilities, but there should be no insuperable difficulties in the way of applying the principle with varying degrees of perfection according to the conditions obtaining throughout the country. The factor of expense cannot be neglected. It is essential that the tests be made by a pathologist of experience; at the same time a Wassermann test can be done, and an adequate physical examination carried out. Every volunteer should receive a card stating his blood-group, and a record should be kept at the hospital of his address, &c. If the investigation be made of "batches" the expense is trifling. It is remotely possible that the Ministry of Health may consider the project worthy of consideration.

I am aware that efficient provision has been made for this contingency at certain hospitals; I have in mind, however, the organised registration of donors drawn from large works or other more or less stable communities. I am, Sir, yours faithfully,

H. H. GREENWOOD, B.S. Lond., F.R.C.S. Eng.,
Consulting Surgeon, G.W.R. Hospital; Hon. Surgeon,
Victoria Hospital, Swindon.

Sept. 7th, 1923.

A MEDICAL AND NURSING SERVICE IN RURAL MANITOBA.

To the Editor of THE LANCET.

SIR,—I think your readers will be interested in a brief account of a combined medical and nursing service organised for rural areas by the Manitoba Division of the Canadian Red Cross Society, especially as it has been of tremendous assistance to many British-born settlers whose wives in many cases have come directly from the Old Land to live in what are known as the unorganised areas of Manitoba. It illustrates also the value of the whole-hearted coöperation of the medical profession with the Red Cross peace-time service.

In 1919 the Red Cross Society, finding a great and urgent demand for some sort of skilled assistance in dealing with the health of certain districts which had no other civilised social service, established at Reynolds, where Poles and Ruthenian settlers abound, 63 miles east of Winnipeg, Fisher Branch, 72 miles N.W. and Grahamdale, 134 miles N.W. (both points lying between Lakes Winnipeg and Manitoba), and also at Kinosota, 140 miles N.W., on the west side of Lake Manitoba, nursing stations, which were at first disciplined and managed by the Provincial Board of Health but now are under the exclusive management of the Red Cross Society with its Medical Advisory Board. These nursing stations proved of great value, but it soon became apparent that medical supervision was needed and that too great a responsibility was being placed on nurses whose calling does not include the ability to diagnose and to decide the final destination of any given case. It must be remembered that these districts, except Reynolds, were 40 miles at least from the nearest doctor and that very few of the people could afford to pay any fees. The problem was how to cover the ground effectively. For most of the year the roads are only passable by foot or horse-drawn vehicles, and not always thus. Bush country in unorganised Manitoba is always very boggy in spring and often in summer; in winter snow may block the trails. At the request of the Red Cross Society the Winnipeg Medical Society appointed an advisory committee of five doctors who had had a wide experience of rural conditions in Manitoba, under the chairmanship of one of the leading surgeons. After examining such propositions as the organisation of a travelling hospital the medical committee declared itself in favour of appointing a medical officer to the Unorganised Areas Service, who should be paid an ample salary with free transport, give full-time service without other remuneration, and make Winnipeg his headquarters, whence he should visit in turn or as occasion demands these or other nursing stations established by the Red Cross Service. This recommendation was adopted and financed entirely by the Red Cross Society, with the exception that the Winnipeg Medical Society presented the service with the necessary outfit of instruments for midwifery as well as for medical and surgical purposes. Since the fall of 1920 a succession of well-trained young medical men have manned this service to the great comfort and support of the nurses and to the relief of hundreds of settlers and their families.

Here I would like to emphasise the splendid services of our nurses, many of whom have been trained in the Old Country and have proved the value of their training for the C.M.B. diploma when handling the inevitable midwifery perforce single-handed and under difficult conditions. As an eloquent sample of the appreciation of this service to unorganised areas the following is a quotation from a recent letter to the present writer:—

> "The Red Cross people have done a great work here. It is so comforting to us to have the nurse near us and the doctor's monthly visits. This spring the trails have been awful; the land is too wet to seed and now the meadows are too wet to cut the hay. Our post office is 3½ miles away but we have to go about seven miles to get there! Nurse has done fine work since she came here; has visited hundreds in all kinds of weather by land and lake; has been caught in storms and tumbled into snow-drifts, stuck in sloughs, and got lost on several occasions in happy ignorance of the danger! Few nurses would have gone through it, cold and hungry many a time, and no complaints, night and day. In fact she has had as many escapades as St. Paul!"

This is not exaggerated, and refers, of course, only to the unorganised parts of Manitoba. My committee consists of Dr. Jasper Halpenny (chairman), Drs. N. W. Warner, G. S. Fahrni, T. C. Brereton, and myself.—I am, Sir, yours faithfully,

H. M. SPEECHLY, M.R.C.S. Eng.,
Hon. Secretary, Medical Advisory Committee.

Winnipeg, August 22nd, 1923.

PATHOLOGICAL DEPARTMENTS.

To the Editor of THE LANCET.

SIR,—On this subject communications appeared last week in THE LANCET which call for comment.

The utilisation of university pathological departments for money-making may bring them into competition with the pathological departments of county hospitals in an unfair manner. This hospital, for instance, has a fully equipped pathological and bacteriological department with a specialist in charge, who is only allowed to practise as such and whose livelihood depends on this practice. There is a V.D. clinic in the hospital, a few yards from the laboratories, but bloods for Wassermanns *must* be sent to a distant university. The Ministry of Health refuses to allow the county council to pay the hospital department for Wassermann tests in spite of the representations of the county M.O.H., the County Public Health Committee, the clinic medical officers, and the medical and surgical staff of the hospital. The result is that the clinic bloods are "split" and with the hospital bloods (not "split") are done weekly as a matter of routine by the pathologist, who though unpaid, is not without honour in his own laboratory when reports differ. "Seeing the wheels go round" is preferred to a five-shillings-in-the-slot postal machine delivering a piece of pasteboard!

The position is the same in an adjoining county, and will no doubt be the same in a third county which is considering the appointment of a county pathologist.—I am, Sir, yours faithfully,

Salisbury, Sept. 10th, 1923. H. ST. ARNAUD AGATE.

DEFATTED BACTERIAL VACCINES.

To the Editor of THE LANCET.

SIR,—In a lecture delivered on June 14th at St. Mary's Hospital, Prof. G. Dreyer claimed to have made an important discovery by using defatted tubercle bacilli as antigen for diagnostic and therapeutic purposes in tuberculosis. This work has been enthusiastically received by the whole press, and may arouse hopes that will not be satisfied. The Institute of Microbiology in Saarbrücken has been working on very similar lines for years and the use of defatted tubercle bacilli has proved a delicate matter. I should therefore be very much obliged if you will allow me to indicate two things that will lead to a sober valuation of Prof. Dreyer's investigations.

In 1921 [1] and 1922 [2] I published experiments that demonstrated the necessity of defatting tubercle bacilli before using them as specific antigen. I described then a special method of defatting tubercle bacilli by means of the vapours of ether or other fat-dissolving liquid, and was able to show that in this process the biologic albumin of the bacilli remains intact and unaltered. The defatted tubercle bacill form a stable emulsion that is specifically precipitated by the serum of tuberculous persons and this so-called "tuberculo-diagnosticum" is already in constan use at many sanatoria and by medical officers to schools. The same emulsion gave complemen deviation when brought in contact with serum from tuberculous persons and showed remarkable effect when used as anti-tuberculous vaccine in men.[3] These facts have been fully confirmed by Wassermann,[4] who used another process of defatting the tubercle bacilli. Of the earlier publications recommending defatted tubercle bacillus as specific antigen, Prof. Dreyer's observations appear to be a confirmation.

---

[1] Annales de l'Institut Pasteur, xxxv., 797.

[2] Deutsche Archiv für klinische Medizin, cxxxviii., 229.

The second and more remarkable point in Prof. Dreyer's lecture is the fact that his tuberculous antigen withstands exposure for four hours and more to 100° C., at which temperature tubercle bacilli must, according to him, be boiled with formalin and acetone if they are to lose their acid resistance.[5] Up-till now bacteriologists have always carefully tried to avoid as much as possible any alteration of the antigen contained in the living microbe, the immunising power of which is demonstrated to us daily by practical experience. That Prof. Dreyer's boiled tuberculous antigen still possesses the same immunising power is a real discovery of highest theoretical importance, unless further investigation should prove that his good results are due rather to the effect of a protein than of a real immune-therapy.

I am, Sir, yours faithfully,

Saarbrücken, Sept. 4th, 1923. W. FORNET.

Medical News.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A fortnight's "Refresher" Course in general medicine and surgery will be given at the London Temperance Hospital in conjunction with Bethlem Royal Hospital, North-Western Fever Hospital, and the Royal Westminster Ophthalmic Hospital from Oct. 8th to 20th. The course will include daily lectures and clinical demonstrations in the wards and out-patient department. A course on genito-urinary diseases will be given at St. Peter's Hospital from Oct. 1st to 27th. In addition to demonstrations in the out-patient department a series of lectures will be given on various aspects by the members of the staff. A course of eight lectures on tropical diseases will be given by Dr. G. Low and Dr. P. Manson-Bahr at the School of Tropical Medicine, beginning on Tuesday, Oct. 2nd. The subjects considered will be the more important diseases of tropical countries. A course in laryngology, rhinology, and otology, consisting of clinical demonstrations, lectures, &c., each day from 9.30 A.M. to 5 P.M., will be given at the Central London Throat, Nose, and Ear Hospital from Oct. 8th to 26th. A further course on children's diseases will be given at the Victoria Hospital for Children from Oct. 8th to 20th, and in ophthalmology at the Royal London Ophthalmic Hospital from Oct. 8th to Nov. 3rd. The National Hospital for Diseases of the Heart and St. Mark's Hospital for Diseases of the Rectum will each give a fortnight's course on cardiology and proctology respectively, from Oct. 15th to 27th. Copies of the syllabus and further particulars regarding any of the above courses will be forwarded on application to the secretary to the Fellowship of Medicine at 1, Wimpole-street, London, W. 1.

LEBANON HOSPITAL.—Great Britain, America, Holland, and Switzerland all share in the work of the Lebanon Hospital for Mental Diseases, Asfuriyeh, Beyrout, Syria, and the report for the twelvemonth ended March 31st, 1923, shows that the institution has accomplished much good work. During the year under notice there were 279 patients under treatment including 181 new patients, of whom 132 were men and 49 women. Dr. H. Watson Smith, the medical director, states that the increase in the number of women patients necessitated the squeezing in of additional beds in the American and Philadelphia pavilions to accommodate them, and so resulted in an unavoidable congested condition of these houses. The opening of the Strawbridge Memorial House for women patients fortunately relieved this state of affairs. The general statistics show that 38 men and 18 women recovered, and that 49 men and 5 women benefited by their stay in the hospital, while 26 men and women left the hospital for various reasons. The needs of the institution include a permanent and adequate water-supply at an estimated cost of £1000, an X ray plant at £500, a laundry at £1000, and a septic tank at £100. The address of the general secretary is at the Lebanon Hospital Office, 35, Queen Victoria-street, London, E.C.4.

ROYAL DENTAL HOSPITAL OF LONDON.—The prize distribution of the London School of Dental Surgery will take place at the hospital on Oct. 1st at 5 P.M., when Dr. Christopher Addison will distribute the prizes.

SMALL-POX IN ENGLAND AND WALES.—In the week ended Sept. 1st 21 cases of small-pox were reported in England and Wales, ten of these being from Gloucester. Three cases were reported in London on Sept. 7th, one each from Paddington, Finsbury, and Camberwell respectively, and in the five days following five further cases and two suspects came to light. The Camberwell patient was employed at a London hotel, and two cases in Westminster and Lewisham have been attributed to the same source. Infection in the others has been traced to a visitor recently arrived from Spain, whose indisposition was not recognised until the maid who attended her was found to be suffering from small-pox.

THE LATE DR. CLARENCE ROBINSON.—Dr. Robinson, who died suddenly at the early age of 42 on August 29th while on holiday in the Isle of Man, was a popular practitioner in Warrington. A native of Cork, he qualified L.R.C.P. & S. Irel. from Queen's College in 1903 and was appointed house surgeon at the General Hospital, Ramsgate, afterwards becoming visiting surgeon to the Ramsgate and St. Lawrence Dispensary. He went into partnership in general practice at Camberwell Green, and about 15 years ago migrated to Latchford, Warrington, where he became surgeon to the Warrington Infirmary, a member of the panel committee, and surgeon to the pensions board. In the early days of the war he worked at the Lord Derby War Hospital at Winwick, and afterwards served for five years at Thelwall Heys. He leaves a wife and two sons.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE, SPECIAL COURSE IN INFANTS' DISEASES, at the Infants Hospital, Vincent-square, Westminster, S.W.

MONDAY, Sept. 17th.—2–3.30 P.M., Dr. William Robinson: Congenital Heart. 4.30–6 P.M., Dr. Eric Pritchard: Premature Infants, Management and Feeding.

TUESDAY.—2–3.30 P.M., Dr. Eric Pritchard: Syphilis in Infants. 4.30–6 P.M., Mr. Philip Franklin: Tonsils and Adenoids. Demonstration and Operation

WEDNESDAY.—2.30–3.30 P.M., Dr. Helen Mackay: Special Cases in Wards and Out-patient Department (Diabetes and Insulin Treatment, Mongolism, Malaria, Enlarged Thymus, &c.). 4–6.30 P.M., Dr. Donald Paterson: Lecture: Encephalitis and Poliomyelitis.

THURSDAY.—2–3.30 P.M., Dr. Donald Paterson: Special Cases (Wind Swallowing). 4.30–6 P.M., Mr. M. S. Mayou: Lecture and Demonstration: Some Common Eye Conditions from the Practitioner's Point of View.

FRIDAY.—2–3.30 P.M., Dr. Eric Pritchard: Round Table Consultation. Special Cases for Diagnosis. 4.30–6 P.M., Dr. Donald Paterson: Summer Diarrhœa.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, Sept. 17th.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2.30 P.M., Dr. Saunders: Medical Wards.

TUESDAY.—12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Department. 2.30 P.M., Dr. Pritchard: Medical Wards.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 2 P.M., Dr. Burnford: Medical Wards. 3 P.M., Dr. Pernet: Skin Department.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Mr. Dudley Buxton: Dental Department. 2 P.M., Dr. Burrell: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

Appointments.

PANTING, L. C., M.D., B.Ch. Oxf., M.R.C.P. Lond., F.R.C.S. Eng., has been appointed Honorary Consulting Surgeon to the Helston and District Cottage Hospital.

ROBERTS, C., M.B., B.S. Lond., F.R.C.S. Eng., one of the Medical Referees under the Workmen's Compensation Act for County Court Circuits No. 5 and 8.

Certifying Surgeons under the Factory and Workshop Acts:
MACKAY, W. M., M.B., Ch.B. Edin. (Crook, Co. Durham);
FOXTON, H., M.B., Ch.B. Leeds (Uttoxeter).

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth Infirmary, &c.—H.S. £200.
Aylesbury, Royal Bucks Hospital.—R.M.O. £200.
Barbados Parish of St. Andrews.—M.O. £300.
Benenden (Kent) National Sanatorium.—Res. Asst. M.O. £250.
Bradford Royal Infirmary.—H.S. £150.
Central London Ophthalmic Hospital, St. Pancras, W.C.—H.S. £100. Jun. H.S. £50. Also X Ray O.
Dover Royal Victoria Hospital.—H.S. £180.
Dreadnought Hospital, Greenwich.—H.S. and H.P. Each £150.
East African Medical Service.—M.O. £600.
Hackney Metropolitan Borough.—M.O. for Infant Welfare Centre.
Ipswich County Borough.—Sen. Asst. M.O.H., &c. £600.
London County Mental Hospital Service.—Seventh Asst. M.O. £432.
London Jewish Hospital, Stepney Green, E.—Hon. Asst. P., Hon. S. Also Asst. to Out-Patients. £100.
Manchester, Ancoats Hospital.—Res. M.O. £200. Med. Reg. £100.
Manchester Royal Hospital, Salford.—R.M.O. £200. Two H.S.'s and Cas. H.S. Each £150.
Manchester, Royal Infirmary.—Surgical Tutor. £30.
Middlesex Hospital, W.—Radium O. £300.
Mount Vernon Hospital for Diseases of the Chest, Northwood, Middlesex.—Asst. P.
Newcastle-on-Tyne Dispensary.—Hon. Phys.
Nottingham City Education Committee.—Jun. Asst. Med. Insp.
Prince of Wales's General Hospital, Tottenham, N.—H.S. £150. H.P. £150. Also J.H.S. and J.H.P. £110 each.
Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. H.S. £100.
Royal National Orthopœdic Hospital, 234, Great Portland-street, W.—H.S. £150.
Royal Naval Medical Service.—Surgeon-Lieutenants.
Saint Pancras Dispensary, 39, Oakley-square, N.W.—Hon. S.
Walsall County Borough.—Asst. M.O.H. £650.
West African Medical Service.—M.O. £660.
West Bromwich and District Hospital.—Res. Asst. H.S. £180.
Wolverhampton and Staffordshire Hospital.—Res. M.O. £150.

Births, Marriages, and Deaths.

BIRTHS.

BURTON.—On Sept. 8th, to the wife of A. H. G. Burton, M.D., of 13, Beaufort-gardens, Ilford—a daughter.

GRAHAM-STEWART.—On Sept. 4th, at Northdown-avenue, Cliftonville, Margate, the wife of A. Graham-Stewart, M.B., Ch.B., of a son.

HUGHES.—On Sept. 6th, at Heylands, Chagford, Devon, the wife of Dr. H. Ll. Glyn Hughes, D.S.O., M.C., of a daughter.

STOKES.—On Sept. 4th, at Restholme, Cantelupe-road, Bexhill-on-Sea, the wife of Dr. Kenneth Stokes, of a daughter.

WARRICK.—On Sept. 1st, at Blackheath, the wife of R. W. Warrick, M.B., B.S., of a son.

MARRIAGES.

BAXTER—STOPS.—On Sept. 5th, at Emmanuel Church, Didsbury, Manchester, Stephen Edw. Baxter, M.R.C.S., L.R.C.P., to Ruth Jessica, second daughter of the late T. S. Stops, J.P., of Tiffield, Towcester, Northants.

BLAIR—HENDERSON.—On Sept. 5th, at St. Cuthbert's Church, Colinton, Edinburgh, R. G. Blair, M.C., M.B., to Nicolina Margaret, daughter of W. R. Henderson, of Chisholme, Roxburghshire, and Menld, Oxton, Cheshire, and Mrs. Henderson.

BROWNE—BOTT.—At Grange-in-Borrowdale, on Sept. 5th, Leonard Foster Browne, M.D., of 9, Harley-street, W., to Violet, fourth daughter of the Rev. Richard Bott, of Cotehill, near Carlisle.

MCCAUSLAND—SIMSON.—On Sept. 10th, in London, by special licence, Dr. Albert McCausland, of Swanage, to Miss Mildred Spicer Simson.

MCNEE—LE BAS.—On Sept. 4th, at the Chapel of the Charterhouse, London, John W. McNee, D.S.O., M.D., to Geraldine Z. L. Le Bas, only child of the late Cecil H. A. Le Bas and of Mrs. Le Bas, 20, Ridgmount-gardens, London.

ROBERTSON—BLACK.—On Sept. 1st, at Holy Trinity Church, Skirbeck, Boston, Dawson Cameron, M.B., Ch.B., to Ethel Freda Ogle, only daughter of Mr. and Mrs. Arthur Black, Burton House, Boston.

TRAVERS SMITH—IEVERS.—On August 4th, in London, Richard Travers Smith, M.D., F.R.C.P.I., of 17, Harcourt House, Cavendish-square, W. 1, to Ernesta Carlotta Nina, widow of James Butler Ievers, of Quinville Abbey, Quin, Co. Clare, younger daughter of the late Surgeon-General George Whitla, of The Drive, Hove, and Mrs. Whitla.

DEATHS.

HARTRIDGE.—On Sept. 8th, at Wimpole-street, W. 1, Gustavus Hartridge, F.R.C.S., aged 73 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

SOME BEARINGS OF ZOOLOGY ON HUMAN WELFARE.*

BY PROF. J. H. ASHWORTH, F.R.S.

THE bearings of zoology on human welfare—as illustrated by the relation of insects, protozoa, and helminths to the spread or causation of disease in man—have become increasingly evident in these later years.

Arthropods as Carriers of Disease.

At the time of the last meeting of the British Association in Liverpool, held in the year 1896, insects were suspected of acting as transmitters of certain pathogenic organisms to man, but these cases were few and in no single instance had the life cycle of the organism been worked out and the mode of its transmission from insect to man ascertained. Sir Patrick Manson, working in Amoy, had shown (1878) that the larvæ of *Filaria bancrofti* undergo growth and metamorphosis in mosquitoes, but the mode of transference of the metamorphosed larvæ was not determined until 1900. Nearly two years after our last meeting here the part played by the mosquito as host and transmitter of the parasite of malaria was made known by Ross. In addition to these two cases at least eight important examples can now be cited of arthropods proved to act as carriers of pathogenic organisms to man—e.g., Stegomyia—yellow fever, Phlebotomus—sandfly fever, tsetse-flies—sleeping sickness, Conorhinus—South American trypanosomiasis (Chagas's disease), Chrysops—*Filaria (Loa) loa*, the flea *Xenopsylla cheopis*—plague, the body louse—trench fever, relapsing fever, and typhus, and the tick Ornithodorus—African relapsing fever. In selecting examples for brief consideration I propose to deal very shortly with malaria, although it is the most important of the insect-carried diseases, because the essential relations between the Anopheles mosquito and the parasite are known to everyone here. There still remain lacunæ in our knowledge of the malarial organisms. Ross and Thomson (1910), working in this city, showed that asexual forms of the parasite tend to persist in small numbers between relapses, and suggested that infection is maintained by these asexual stages. Such explanation elucidates those cases in which relapses occur after short intervals, but the recurrence of the attacks of fever after long intervals can only be explained by assuming that the parasites lie dormant in the body—and we know neither in what part of the body nor in what stage or condition they persist. Nevertheless, the cardinal points about the organism are established, and preventive measures and methods of attack based on a knowledge of the habits and bionomics of Anopheles have been fruitful in beneficial results in many parts of the world.

Knowledge of the Methods of Disease Transmission.

If we desire an illustration of the vast difference to human well-being between knowing and not knowing how a disease-germ is transmitted to man, we may turn to the case of yellow fever. When this pestilence came from the unknown, and no one knew how to check it, its appearance in a community gave rise to extreme despair and in many cases was the signal for wholesale migration of those inhabitants who could leave the place. But with the discovery that Stegomyia was the transmitting agent all this was changed. The municipality or district took steps to organise its preventive defences against a now tangible enemy, and the successful issue of these efforts, with the consequent great saving of life and reduction of human suffering in the Southern United States, in Panama, in Havana, and in other places, is common knowledge. It is a striking fact that during 1922 Central America, the West Indies, and all but one country of South America were free from yellow fever, which has ravaged these regions for nearly two centuries. The campaign against Stegomyia is resulting, as a recent Rockefeller report points out, in yellow fever being restricted to rapidly diminishing isolated areas, and this disease seems to be one which by persistent effort can be brought completely under control.

Refinements of Entomological Research.

The relation of fleas to plague provides one of the best and most recent illustrations of the necessity for careful work on the systematics and on the structure and bionomics of insects concerned in carrying pathogenic organisms. Plague was introduced into Bombay in autumn 1896, and during the next two years extended over the greater part of Bombay Presidency and was carried to distant provinces.

---

* A section of the Presidential Address delivered to the Section of Zoology, British Association for the Advancement of Science, at the annual meeting in Liverpool on Sept. 13th.

The Indian Government requested that a Commission should be sent out to investigate the conditions. This Commission, which visited India in 1898–99, came to the conclusion (1901) that rats spread plague and that infection of man took place through the skin, but—and this is amazing to us at the present day—“ that suctorial insects do not come under consideration in connexion with the spread of plague.” Further observations, however, soon showed this conclusion to be erroneous. Liston found in Bombay in 1903 that the common rat-flea was *Pulex* (*Xenopsylla*) *cheopis*, that it was present in houses in which rats had died of plague and n which some of the residents had become infected, that the plague bacillus could multiply in the stomach of this lea, and that the flea would—in the absence of its usual host—attack man. These observations pointed to the mportance of this flea in the dissemination of plague, and the Second Plague Commission, which was appointed and began work in 1905, definitely proved that *Xenopsylla cheopis* is the transmitter of the plague organism from rat to rat and from rat to man. The mechanism of transmission of the plague bacillus was worked out by Bacot and Martin n 1913. Subsequent research has shown that all fleas of the genus *Xenopsylla* living on rats are not of the one species. n plague areas it was found that *X. cheopis* was the common lea, while *X. astia* was the prevalent species in those districts which had remained free from plague or had suffered only ightly.

The distinction of *X. cheopis* from *X. astia* is not an ntomological refinement with purely systematic significance, but corresponds with a different relation of the species to the pidemiology of plague, and hence becomes a factor of great practical importance. If through these researches it has become possible by examination of the rat-fleas of a locality o estimate accurately its liability to plague, anti-plague measures may henceforward be restricted to those areas in which plague is likely to occur—i.e., where *cheopis* is the redominant flea. Thus a great economy of effort and of xpenditure and a higher degree of efficiency may be chieved ; in fact, the problem of the prevention or reduction f plague may be brought from unwieldy to practicable roportions. When it is remembered that since we last met n Liverpool some 10¼ millions of people have died in India rom plague we have a more than sufficient index of the nportance of a precise knowledge of the systematics, tructure, and bionomics of the insect-carrier of *Bacillus pestis.*

Classification of Protozoa.

Another of the outstanding features of the period under review has been the extensive and intensive study of the Protozoa. The structure and the bionomics and life-history f these organisms have been investigated with the help f the finest developments of modern technique. It is fitting ere to record our acknowledgement to two staining methods —Heidenhain’s iron-hæmatoxylin and the Romanowsky ain (including Giemsa’s and Leishman’s modifications), hich have added greatly to our technical resources.

There is time to refer only to certain of the Protozoa hich directly affect man. Twenty years ago our knowledge f the few species of Protozoa recorded from the human imentary canal was defective in two important respects—he systematic characters and the biology of the species—o there was much confusion. Subsequent investigations, nd especially those of the last ten years (by Wenyon, Dobell, nd others), have cleared up most of the doubtful points, ut owing to the difficulties of size and the paucity of haracters available it is by no means easy in practice to stinguish certain of the species. Of the 17 species now nown to occur in the intestine of man *Entamœba histolytica* s received particular attention. This organism lives as a ssue parasite in the wall of the large intestine, where, as a le, the damage caused is counterbalanced by the host’s generative processes. But when the destruction outstrips e regeneration intestinal disturbance results, leading to e condition known as amœbic dysentery.

In all work with human Entamœbæ there is need for itical determination of the species, for, in addition to *histolytica*, a closely similar species, *E. coli*, is a common habitant of the intestine. This, however, is a harmless mmensal, feeding on bacteria and fragments derived from e host’s food. The distinction between the two species sts chiefly upon the characters of the nuclei and of the ature cyst—quadrinucleate in *histolytica* and octonucleate *coli*—and considerable care and technical skill are requisite many cases before a diagnosis can be given. And yet this stinction is definitely necessary in practice, for indis- minate treatment of persons with Entamœbæ is indefen- ble ; treatment is only for those with *histolytica ;* it is eless for those with *coli*, and subjects them needlessly to unpleasant experience.

A notable result of recent work is the proof that the more mmon intestinal protozoa, formerly believed to be restricted warmer countries, occur indigenously in Britain. This was st established by a group of observers in this city, and has en confirmed and extended by subsequent workers. There is good reason for believing that in this country the incidence of infection with *E. histolytica* is about 7 to 10 per cent., and with *E. coli* about five times as great (Dobell).

Mode of Entry of Parasitic Worms.

Of the problems presented by the parasitic worms the most momentous are those associated with Ankylostoma and its near relative Necator, which are prevalent in countries lying between 36° N. and 30° S.—a zone which contains more than half the population of the earth. Heavy infection with Ankylostoma or with Necator produces severe anæmia, and reduces the host’s physical and mental efficiency to a serious degree. Until 1898 there was no suggestion that infection was acquired in any other way than by the mouth, but in that year Looss published his first communication on the entry of the larvæ of Ankylostoma through the skin, and in 1903 gave an account of further experiments which proved that dermal infection resulted in the presence of worms in the intestine. At the meeting of this Association in Cambridge in 1904 Looss demonstrated to a small company his microscopical preparations showing the path of migration of the larvæ. His investigations served to establish the importance of the skin as the chief portal of entry of Ankylostoma, and pointed the way to effective methods of prevention against infection.

Another notable advance in helminthology is the working out of the life-cycle of Schistosoma (Bilharzia)—a genus of trematode worms causing much suffering in Egypt and elsewhere in Africa, as well as in Japan and other parts of the world. We owe chiefly to Leiper’s work (1915–16) our knowledge of the life-history and method of entry into man of the Egyptian species of Schistosoma. He demonstrated that two species of this parasite occur in Egypt, and established that the miracidia develop in different intermediate hosts : those of *S. mansoni* enter Planorbis, while those of *S. hæmatobium* penetrate into Bullinus—the molluscs being abundant in the irrigation canals. The sporocysts produce cercariæ, which escape from the snails and gather near the surface of the water, and experiments with young mice and rats showed that the cercariæ attach themselves to the skin, enter, and reach the portal system, from which they travel to the veins of the lower part of the abdomen. Infection of man takes place chiefly through the skin when bathing or washing in water containing the cercariæ, though infection may also occur through drinking such water. And so, at last, these worms which have troubled Egypt for at least 30 centuries have become known in all their stages, and measures for preventing infection—which were of great use during the war—have been devised and curative treatment introduced.

The period under review has obviously been one of great activity in research on helminths, and fertile in measures tending to reduce the risks of infection. Insects, protozoa, and helminths not only inflict direct injury on man ; they also diminish his material welfare by impairing the health or causing the death of his horses, cattle, and sheep, by destroying food crops during growth and, in the case of insects, by devouring the harvested grain. The measure of control which man can gain over insects, ticks, and endoparasitic organisms, will determine largely the extent to which he can use and develop the natural resources of the rich tropical and sub-tropical zone of the earth.

Other applications of zoology to human well-being cannot be dealt with owing to lack of time, but mention should be made of two—the researches on sea-fisheries problems which have formed an important branch of the zoological work of this country for 40 years, and the studies on genetics which made possible an explanation of the mode of inheritance of a particular blood group, and of some of the defects (e.g., colour-blindness and hæmophilia) and malformations which appear in the human race.

COLONIAL HEALTH REPORTS.

Sierra Leone.[1]

THE population of Sierra Leone at the census taken in 1921 was 85,163, of whom 44,142 dwelt in Freetown, the capital. The European resident population in the colony numbered 1161. The general health of both European and African officials compares rather unfavourably with that of the previous year. While the death-rates were lower, the invaliding and general sick-rates and ineffectiveness were higher ; and though the total number of cases of illness treated showed a decrease of 5837 as compared with 1920, this is said to have been due to some extent to the closing of certain dispensaries. There was a mild outbreak of small-pox between April and June, 31 cases with one death, and an increase in malaria of 218 cases. Dysentery showed a marked decrease, from 404 cases in 1920 to 185 in 1921 ; it has almost disappeared from Freetown prison. Helminthic diseases are very prevalent, especially ankylostomiasis, of which there were 118 cases ; eucalyptus oil appears to be efficacious in treatment, also thymol, or beta-naphthol, or both. The health of prisoners is stated to have been "most unsatisfactory" for part of the year ; in the Freetown prison the sick-rate was 66·03, and the death-rate 78·66 per 1000 of average strength, the daily average number in custody being 318. Towards the end of the year, however, the health conditions improved, and dysentery became "almost negligible." Among the European troops in the colony there was not a single death ; the chief cause of sickness was malaria (195 cases). Among the non-European troops venereal disease (179 cases) and malaria (66 cases) were the most prevalent affections.

---

[1] Annual Medical and Sanitary Report, 1921. Freetown Government Printing Office. 19[illegible].

The report states that it is difficult to get suitable men for the sanitary service, which is not popular. Progress was made in anti-malarial work at Freetown ; "92,378 houses were inspected, resulting in the discovery of 483 breeding places." As the population of the town is stated as 44,142, it is to be presumed that this means "house-inspections," not individual houses. Oiling of cesspits was carried out, and a mixture of kerosene and "solido disinfectant fluid" was found to be very useful ; the two fluids mix well, and fly breeding is prevented as well as that of mosquitoes. A slight outbreak of small-pox occurred in Freetown (26 cases) ; this was probably due to introduction of infection from Grand Bassa (Liberia). Vaccination does not appear to be satisfactory. In the colony there were 35,989 children vaccinated during the year ; in 10,917 the operation was successful, in 6794 unsuccessful, but 18,278 other children were not inspected ; even in Freetown, out of a total of 14,708 there were 9653 not inspected. When small-pox became epidemic in Freetown Police District vaccination was made compulsory. There has been a great reduction in the prevalence of dysentery ; only 184 cases were treated in Government institutions in 1921, as compared with 394 in 1920, and 574 in 1918. On account of the prevalence of intestinal disorders in Freetown an extensive examination of tinned foodstuffs was carried out, with the result that several thousands of articles were destroyed by order of the magistrate, including 5764 tins of sardines and 132 barrels of biscuits. It is disquieting to hear that there was a scarcity of water at Freetown from the middle of March to the middle of May, and that the city was placed on a restricted supply. "The problem of further increasing the water-supply will sooner or later have to be faced and seriously grappled with." To an outside observer it would appear to be a matter requiring immediate action. The average maximum temperature at Tower Hill, Freetown, was 91° F. in February and March, and 90° in January and April ; in January and February no rain fell at all, and in March only 0·11 inch. A restricted supply under such conditions would entail hardship, and might be most detrimental to health. On the other hand, it is encouraging to learn that a model village, the first of its kind, has been laid out at Giema, under the local Chief (who had been educated at the school for the sons of Chiefs). It is, of course, not perfect in all respects, but "is one of the best laid out and cleanest villages the senior sanitary officer has seen in Sierra Leone." Dr. J. Beringer concludes his report by urging the necessity for a hospital for infectious diseases at Freetown ; the only accommodation now available is quite unsuited for the purpose.

Weihaiwei.

This territory, leased to Great Britain by China in 1898, is part of the province of Shantung. and comprises a strip of land 10 miles wide, with a coastline of 72 miles. The island of Liukung, lying east and west across the bay, is also included in the territory, and affords excellent shelter from the sea. Port Edward, on the mainland, is the only port, and is also the seat of government. The total area of the territory is 288 square miles, and the native population at the census of 1921 was 154,416. The foreign population is mainly British, and varies from a small number in winter to several hundreds in summer, when visitors arrive from all parts of China in order to enjoy the salubrious climate. In addition, several thousand personnel of the China Squadron spend a few months each summer in the territory. The summer of 1922 was exceptionally hot, but the rainfall was just above the average. General health conditions among the residents and visiting European population on the mainland were exceptionally good. Apart from three cases of dysentery, there were no cases of infectious diseases. There was one birth and one death. There were several cases of septic sore-throat, probably of an infectious nature, affecting only newcomers to China. The health of the native population was good. During the first and the last two months of the year a number of mild cases of influenza were treated. The number of cases of dysentery and diarrhœa treated was 256, as compared with 350 in the previous year. There were 31 persons holding licences to smoke opium, their average age being 63. The highest mean temperatures in 1922 were 80 in June and 86 in July and August. Rain or snow fell on 78 days, with a total rainfall of 24·84 inches. The snowfall in November was 3 feet, the deepest within the memory of any inhabitant.

Gambia.

In a report prepared by Mr. C. R. Workman, Colonial Secretary, on the affairs of the Colony and Protectorate for the year 1922, it is recalled that the Gambia, though the smallest, is the oldest of the possessions of England in Africa. The population of Bathurst, the chief town, is 9395, with 205 Europeans. The death-rate in 1922 was 46·62 per 1000, the average since 1916 having been 42 per 1000. The chief causes of death were pneumonia and tetanus. Accurate statistics from the Protectorate are not obtainable, but a careful return from the North Bank Province for 1922 gives 1628 births and 905 deaths. In this Province an outbreak of bubonic plague occurred which was traced to a focus in French Senegal ; 34 cases were counted, and only four of them recovered. Active measures were taken to isolate the infected villages, and control stations were established on the route to Bathurst. It was only by vigilance and a strict enforcement of regulations that the capital was saved from a visitation of the disease. The meteorological returns from Bathurst for 1922 showed : Average maximum shade temperature, 92·2° F. ; average minimum shade, 63·4° F. ; average mean, 77·8° F. ; rainfall, 45·71 inches.

THE "MINTITE" PATENT FINISH HOT-WATER BOTTLE.

WE have previously reported upon the heat and acid-resisting qualities of "Mintite" patent finish for articles made of indiarubber. This finish, which is an application of mica, is now used for hot-water bottles, and, in addition to the advantages already mentioned, it is claimed that tensile strength is increased. Hot-water bottles treated by this method should certainly possess a longer life than the ordinary untreated rubber article. The patentee is Mr. Louis Minton, Trevelyan Buildings, Manchester.

Summer Time will cease on Sunday next, Sept. 16th, a 3 A.M., when the clock will be put back to 2 A.M. The hou 2–3 A.M. Summer Time will thus be followed by the hou 2–3 A.M. Greenwich Time. Summer Time will be prolonge in France, Belgium, and Holland until Oct. 6–7th.

Mr. F. F. Burghard informs us that he has retired fro practice and has left London. His permanent address i Craythorne, Rolleston, Burton-on-Trent, Staffs.

Uniped.—The advantages of the all-metal limb do no in the opinion of the Pensions Ministry experts outweig the disadvantage of its high cost. The light metal limb wit wooden socket which was decided upon by the 1921 Com mittee, continues to be supplied and to give satisfaction The wooden Anglesea pattern limb can be made as light o even lighter than the metal limb. Various makers now suppl limbs with metal sockets at a price about the same as tha which the Ministry is prepared to pay.

A Lecture

ON

INSULIN AND ITS VALUE IN MEDICINE.

Delivered before the Section of Physiology of the British Association at Liverpool on Sept. 17th, 1923,

BY J. J. R. MACLEOD, F.R.S., M.B., CH.B. ABERD.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF TORONTO.

AMONG the complex chemical changes which go on in the animal body and upon which life depends, carbohydrates play an essential rôle. Their sources in the herbivorous animals is mainly the cellulose and starch synthesised by plants and in the carnivorous animals it is partly the starch-like substance called glycogen as which they are stored in animal tissues, and partly proteins and, to a less extent fats, from which they are derived by chemical changes occurring in the body. The starch or cellulose taken with the food is resolved by the digestive process into the so-called monosaccharides of which glucose is the most important. The glucose is absorbed into the blood and is carried to the liver and muscles where most of it is converted into glycogen. Between the periods of absorption of glucose the reverse process occurs and glycogen becomes broken down to glucose again, which is then oxidised in the tissues (muscles) so as to produce energy, the final products of this oxidation being carbon dioxide and water. While digestion is proceeding the supply of glucose for oxidation may come directly from the glucose which is being absorbed from the alimentary canal, but of this we cannot be certain. In any case, before it can be oxidised in the tissues the glucose molecule must undergo a series of preliminary changes and it is probable that these proceed step by step in such a manner that a long series of intermediary substances is formed each one of which exists in a certain state of dynamic equilibrium with the others so that an increase, or a decrease, in any one of them will cause a disturbance extending throughout the entire process.

CARBOHYDRATE METABOLISM.

It is a study of these changes that constitutes the subject of the metabolism of the carbohydrates, and the question arises as to how they may be investigated. Glucose and glycogen are the only two intermediary products that accumulate in the body in sufficient quantities to be measurable by chemical means, the glucose being dissolved in the blood and other fluids of the body and the glycogen, deposited in the solid tissues, particularly the liver and the muscles. Our conclusions concerning the metabolism of the carbohydrates have therefore to be drawn mainly from observations on the changes which occur in the quantities of these two substances in the blood, urine and tissues and from the behaviour of the respiratory process of the animal as a whole.

But the metabolism of the carbohydrates does not proceed independently, for, in the chain of processes which precede the final oxidation of glucose, some substance is formed which is also intermediary in the metabolism of the other proximate principles of food—namely, fats and proteins. Through the formation of this intermediary substance transmutation of one proximate principle into another becomes possible, thus carbohydrates may be formed from proteins and fats from carbohydrates. The metabolism of the three proximate principles, therefore, is closely interwoven so that when anything occurs to interfere with that of one of them some change is likely to occur in the others. When the metabolism of carbohydrate becomes upset, for example, that of fats also goes out of order, with the result that incompletely oxidised derivatives, known as the ketone bodies, accumulate in the body and may act as poisons.

A Break in the Metabolic Cycle.

These facts will make it evident that the entire process of metabolism is liable to become upset when anything occurs to prevent the transformation of one of the intermediary carbohydrate substances into the others and this is precisely what occurs in the disease known as diabetes. Somewhere in the series of metabolic processes which precede the oxidation of glucose an essential chemical change fails to proceed rapidly enough to keep pace with the other changes with the result that this sugar accumulates in the blood in which its concentration becomes so high that some is excreted by the kidneys and appears in the urine. Hyperglycæmia and glycosuria, the two earliest symptoms of the disease, are thus explained and for long there may be no other symptom. Usually, however, the fault upon which they depend becomes still more pronounced, so that its effects spread further along the chain of metabolic processes and the final oxidation of glucose fails to occur as is revealed by a failure of the respiratory quotient—the ratio between oxygen and carbon dioxide in the respired air—to become raised as it should following the ingestion of carbohydrates. The metabolism of fats also comes to be interfered with so that they fail to be completely oxidised, so that serious symptoms supervene, known as diabetic coma, due to the toxic action of the ketone bodies. The entire chemical laboratory of life becomes disorganised with the result that the tissues disintegrate, leading to extreme emaciation and to a lowering of the natural resistance of the body against infections, both of which are other symptoms of the disease.

It is evident, therefore, that the immediate problem of diabetes consists in finding the cause for the fault in the chemical processes by which the glucose molecule is prepared for oxidation. Not so much in detecting the exact stage at which this fault occurs, although this is highly important, as in finding out what has gone wrong with the mechanism by which the metabolic process is controlled.

As a result of long years of investigation both in the laboratory and the clinic it has come to be known that many of the chemical processes in the body are controlled by substances called hormones, and it has been supposed that one of these must also control the process of carbohydrate metabolism. The question was to find this anti-diabetic hormone, as we may call it, and it is this which has been achieved in the discovery of insulin.

EARLY FAILURES TO FIND THE ANTI-DIABETIC HORMONE.

The steps which preceded this discovery extend over many years, and there is probably no chapter in the history of medical science that more clearly shows the value of painstaking and patient research, both in the clinic and the laboratory, than that which records these steps. The earlier investigations culminated in 1889, when it was discovered by von Mehring and Minkowski that removal of the pancreas or abdominal sweetbread from dogs causes severe diabetes from which the animals succumb in two or three weeks. The hypothesis was therefore made that the anti-diabetic hormone is secreted into the blood by the pancreas—an internal secretion—and it was soon found that its action must be entirely independent of that of the (external) secretion into the intestine of the powerful digestive juice, since diabetes did not occur when the pancreatic ducts were tied. This independence of the external secretion and the anti-diabetic function of the gland made it seem probable that each is the function of different portions of the gland, and, as a matter of fact, it was known, through the work of Langerhans, which preceded that of von Mehring and Minkowski by some 20 years, that the pancreas contains islets of peculiar cells embedded in the connective tissue lying between the tubules or acini which are the source of the external secretion. Anatomical investigations, particularly by Diamare and Laguesse, demonstrated that these islets of Langerhans, as they came to be called, are present in all the vertebrates, although in some, such as the bony fishes, they exist, not embedded in the pancreas, but as distinct glands situated in the mesentary apart from this organ. The cells composing them were also found to possess characteristic microscopic features. As this work progressed from the anatomical side pathologists discovered that microscopic changes could frequently be detected in the cells of the islets in patients who had died of diabetes, and the surmise that they must produce the internal secretion which controls carbohydrate metabolism became so strong that the name insulin was suggested for it by Sir E. S. Schafer. But so far there was no direct evidence to support the hypothesis that it is by secreting insulin into the blood that the pancreas owes its control over carbohydrate metabolism. This could be furnished most satisfactorily, by showing that an extract prepared from the pancreas or from the principal islets of the bony fishes was capable of removing the symptoms in a depancreated dog or a diabetic patient. Attempts to prepare such extracts by the usual means were, however, without success, and some investigators concluded that the power of the pancreas to control carbohydrate metabolism must depend on some other mechanism, not requiring the internal secretion of insulin. Others attributed the failures in the isolation of this hormone to the fact that it was destroyed during the process of extraction by the powerful digestive ferments which such extracts of the pancreas must also contain. To circumvent the action of these, alcohol was tried as the extractive medium by Zuelzer and by E. L. Scott, and here a certain degree of success was attained, both in the laboratory and in the clinic, when for similar reasons, the extracts were administered subcutaneously instead of by mouth. These investigations, which were made in 1908, were not carried far enough, however, to justify the use of the extracts in the treatment of diabetes, being discontinued because of the dangerous toxic effects which followed their administration to man. Some years prior to this (in 1904) Rennie and Fraser also tried to obtain active extracts by using the principal islets of bony fishes which, as we have seen, are homologous with the islets of Langerhans of the mammalian pancreas. As more recent work has shown that these structures are by far the richest known source of insulin, it is remarkable how near these workers came to success. They failed to convince others partly because they did not have at their disposal the more recently evolved methods for measurement of the percentage of sugar in the blood, and partly because they usually gave, either the fresh glands or extracts of them, by mouth instead of subcutaneously.

Demonstration on Animals.

Discouraged by these repeated failures most physicians gave up all hope that a pancreatic extract capable of removing the symptoms of diabetes would ever be discovered, and the search for insulin became the problem of the physiologist. It was necessary in the first place to demonstrate that such a hormone really exists in the animal body, quite apart from its isolation in extracts. This was achieved in 1916 by A. H. Clark, who compared the rate at which glucose is used by the isolated mammalian heart kept alive by perfusing it with a nutritive fluid alone with that of one perfused with fluid which had previously been passed through the blood-vessels of the pancreas. Decidedly more glucose was found to disappear from the solution that had passed through the pancreas, indicating that a hormone stimulating sugar utilisation must have been added to it.[1] The experiment showed conclusively that the pancreas does produce insulin, and it remained to devise means by which the hormone could be preserved in extracts of the gland. To succeed in doing so required the development of some new and untried method of attack, and this was suggested by F. G. Banting. His plan was to make extracts, not of the fresh normal pancreas, as others had done, but of pancreas which had been caused to undergo partial degeneration by entirely blocking the secreting ducts, previous investigators having shown that this degeneration does not greatly affect the isles of Langerhans, but mainly the cells which produce the digestive juice. With the assistance of C. H. Best, Banting blocked the ducts by tying them in dogs, and some weeks later removed the degenerated pancreas and made extracts from it. When these were injected into other dogs that had been rendered diabetic by removal of the pancreas, it was found that the two main symptoms of the disease, hyperglycæmia and glycosuria, were greatly diminished. This showed with little doubt that the anti-diabetic hormone could be extracted from the pancreas provided its destruction by the digestive ferments was circumvented. The next step was to find methods by which extracts containing it could be made from the intact gland, for, of course, the supply from partially degenerated pancreas could never be sufficient to investigate thoroughly the full physiological action of the extract and thus to determine its possible clinical value. Extracts of early fœtal pancreas were tried by Banting and Best, since it was known that the digestive ferments are absent until shortly before birth. They were found to have the same action as those from the degenerated gland, and this led to a re-trial of alcoholic extracts of the normal undegenerated gland of cattle. Again successful results were obtained, and not only were the hyperglycæmia and glycosuria found to be diminished by the extracts, but by their repeated injection the diabetic animals improved greatly in general condition, and one of them lived for over two months, when it was killed for investigation.

Provided with a larger supply of extract, it now became possible to test its effect on the other symptoms of diabetes in animals. Besides hyperglycæmia and glycosuria, these symptoms are that after feeding with carbohydrates glycogen fails to be deposited in the liver, the relationship between the intake of oxygen and the output of carbon dioxide acid in the respired air—the so-called respiratory quotient—does not become altered. Fats also accumulate in the liver and blood, and, since the carbohydrate fires are burning low, they fail to be completely oxidised and appear as ketone bodies in the urine. These objective symptoms, common to depancreatised animals and diabetic patients, are associated with others of a subjective nature and extreme emaciation. With the invaluable assistance of J. B. Collip, the symptoms were found to be promptly removed by the extract. It has since been found, if insulin be given daily and excess of fat removed from the diet, that the depancreatised animals can be kept alive in excellent nutritive condition for over four months at least.

Application to Man.

These results obtained in the physiological laboratory proved conclusively that the elusive anti-diabetic hormone had been discovered, and that the time had now arrived to see whether the extracts would be equally efficacious in removing the symptoms of diabetes in man. The first attempts to do this were met with the difficulty that the extract caused considerable irritation at the site of injection, so that the injections could not be sufficiently repeated to test their real value although a temporary reduction in the hyperglycæmia and glycosuria were found to occur. The clinical application of the discovery of insulin came to depend on the removal from the alcoholic extracts of pancreas of the irritating substances, and this was achieved by Dr. J. B. Collip by a method of fractional precipitation with alcohol. By the use of the purified preparation it soon became possible to show that the results of the laboratory were precisely duplicated in the clinic, and it will suffice if I describe those obtained by Banting, Best, Collip, Campbell, and Fletcher on a boy of 14 years suffering from the acute form which the disease usually takes at this age. Hyperglycæmia, glycosuria, ketonuria, and extreme emaciation were prominent objective symptoms, and they could not be removed by the most careful dietetic treatment. The boy had lost all interest in his surroundings and lay in bed most of the time. There was little prospect that he could live for many months longer. Injections of insulin given, usually twice daily, from Jan. 23rd to Feb. 4th, 1922, had an immediate effect in removing all of the symptoms, with the exception that small amounts of sugar appeared occasionally in the urine due quite clearly to the fact that sufficient insulin had not been given. "The boy became brighter, more active, looked better, and said he felt stronger," and it was difficult to realise that the serious invalid of yesterday had become the convalescent of to-day.

---

[1] E. J. Starling and others had previously shown that acid extracts of pancreas often caused the isolated heart to use more sugar.

Large Scale Production.

With the aid of the Connaught Antitoxin Laboratories of the University of Toronto work was now started to produce insulin in larger quantities, but the serious difficulties which were encountered made it impossible to obtain enough to treat more than a few cases during the early months of 1922. Later in the year, by collaboration with manufacturing firms in the States, and, through the Medical Research Council in this country the supply became sufficient, so that samples were sent for clinical trial to several hospitals and much information regarding the therapeutic value of insulin in the different forms of diabetes soon became available. These show it to be invaluable in the treatment of acute cases in which the symptoms cannot be removed by the most careful dietetic control. Especially in coma is insulin invaluable, for by stirring up the fires of carbohydrate combustion insulin quickly rids the organism of the ketone bodies to which this, often fatal, symptom is due. Insulin undoubtedly saves the lives of many of these patients. Equally useful has it proved to be in less acute cases in which either, because of dietetic indiscretion, or the incidence of some acute infection such as influenza, the symptoms have become suddenly acute and dangerous.

The milder types of diabetes, which are relatively common in the later years of life, are usually amenable to dietetic treatment alone, and do not require insulin except when complications supervene, such as gangrene or some concurrent acute disease, and it is probable that the constant use of insulin is unnecessary in about three-fourths of all cases of the disease. Its value in the majority of cases is when emergencies arise, for example, by treatment with insulin for some days preceding the administration of anæsthetics for surgical purposes, the grave risks under which the operation was previously conducted in diabetic patients are greatly minimised. But it must not be overlooked that even in the routine treatment of these chronic cases insulin may prove of value. In this connexion it is significant that A. N. Allen, working in my laboratory, has found that the amount of sugar which disappears from the urine for each unit of insulin when it is given to depancreatised dogs in small doses is much greater than with large doses. It may prove useful, therefore, to give small doses of insulin in the more chronic type of case which, for one reason or another, is not responding favourably to dietetic measures alone

Method of Administration.

This naturally raises the question of the method of administration. In acute cases this must be subcutaneously or intravenously so as to circumvent the destruction of insulin by the powerful digestive juices of the stomach and intestine, but it is possible when only small amounts are required, as in mild cases, that sufficient absorption may occur from the skin by applying an ointment, or from the alimentary canal by oral administration.

It is often asked whether treatment with insulin brings about a cure of the disease; does its repeated administration by taking the strain off the endogenous production of insulin by the patient's pancreas allow this gland to recuperate its lost function and so make further use unnecessary? I will not venture to reply to this question in definite terms, for it would be rash to do so from the experience of little more than a year since insulin became available. It is nevertheless significant that regeneration of new islet tissue has been demonstrated by R. R. Bensley to occur in the pancreas of certain laboratory animals months after ligation of the ducts, for although, as we have seen, the acini are mainly affected by this operation, the islets also become involved to be replaced later by new islet tissue. Diabetes, if untreated, is a progressive disease, probably because of the strain which is put upon the remaining, still unaffected, islets to supply enough insulin to metabolise the carbohydrates in circulation. If this faulty balance between insulin and carbohydrate is corrected, either by reducing the carbohydrate supply through dietary regulation or by supplying more insulin from without, the strain on the islets may be so far relieved that they can develop their inherent powers of regeneration.

VALUE OF INSULIN IN METABOLIC INVESTIGATIONS.

Although there can be no doubt of the high therapeutic value of insulin in the treatment of many cases of diabetes, its value as a new instrument for the investigation of other problems of metabolism than those relating to this disease is also high. It furnishes the physiologist with a new instrument for the investigation of the many problems connected with the chemical processes which go on in the body—with a key which may serve to unlock some of the numerous doors which stand in the way to an understanding of the working of the animal machine. Evidence for this belief is founded among other things on the striking effects of insulin on normal animals. When it is administered to rabbits, for example, the first effect is a very rapid lowering in the percentage of sugar of the blood—first observed by J. B. Collip—and when this reaches a certain level symptoms of a peculiar nature supervene. These consist usually of violent convulsive seizures each lasting for a minute or so, and of a gradually increasing state of coma, with a fall in body temperature, ending often in death from respiratory failure. Symptoms of a similar character occur also in other animals, including man, after large doses of insulin. There are often premonitory symptoms and in man these are extreme hunger, anxiety, tremulousness, and, later, quickened pulse and sweating. In searching for the cause of these remarkable symptoms we were guided by the observation, made two years previously by Mann and Magath, that the somewhat similar symptoms which develop in dogs after removal of the liver are dependent on the lowering of blood-sugar and can be relieved by injections of glucose. Could the symptoms following insulin be due to the same cause? We very soon found this to be the case, the evidence being, partly, that they usually supervene in normally fed animals when the blood-sugar has fallen to about 0·045 per cent. and partly that they are removed immediately by the addition of glucose to the blood either by administering this sugar subcutaneously or by causing it to be liberated in the body from glycogen, as by the injection of adrenalin. It was found, moreover, that of all the sugars glucose alone has an immediate and lasting effect, even lævulose and galactose, which are its nearest neighbours, having only a slight and transitory action. The symptoms, therefore, are related to a reduction in the concentration of glucose in the blood and must be dependent upon the consequent lowering of free glucose in certain of the tissues; to a condition of glucatonia, we may call it. Why this should be associated with the development of symptoms which are evidently due to abnormal stimulation of the nerve centres that control muscular action is difficult to explain. It looks as if some toxic substance had developed, whose formation is ordinarily prevented by the presence of free glucose, or it may be that a certain tension of free glucose is essential for the chemical interchanges that are associated with the physiological functioning of the cells, particularly those of the nerve centres. The close similarity of many of the symptoms with those observed in anoxæmia suggests the possibility that interference with the processes of intracellular oxidation is really responsible for the symptoms, and this view is fortified by the fact that the arterial blood becomes intensely venous in colour when the symptoms supervene. Whatever may be their immediate cause, the discovery that the symptoms are related to hypoglycæmia and can be antidoted by glucose proved to be of great practical importance, for it sounded a note of warning in the use of insulin on patients and it provided a certain remedy should similar symptoms supervene as a result. Possibly, also, it explains in part at least the cause for the toxic symptoms on account of which previous observers, such as Zuelzer, had been compelled to abandon their investigations of the value of extracts of pancreas in the treatment of diabetes in man.

Although the symptoms commonly occur in well-fed animals when the blood-sugar is about 0·045 per cent., they may fail to be observed until a much lower level has been reached. This is particularly the case when a large dose of insulin is given some time after food. The liability of symptoms to occur at about 0·045 per cent. of blood-sugar has served as a useful basis for measurement of the dosage of insulin, one unit being defined as the amount which can lower the blood-sugar to the convulsive level of 0·045 per cent. within four hours in rabbits weighing about 2 kg. Since this "physiological" unit, as it is called, is said to be stronger than is necessary for certain clinical purposes it has been decided for the present to use, as the "clinical" unit, one that is one-third the above strength. This question of the physiological assay of insulin is receiving much attention at present.

Cause of Reduction in Blood-Sugar.

These observations clearly pointed the way to the next problem—namely, the cause for the lowering of the blood-sugar. At first it seemed as if this should soon be solved, for, as already mentioned, it had been found by Banting, Best, and Collip that insulin not only causes glycogen to be deposited in the liver of diabetic animals when sugar is given, but also causes the respiratory quotient to become raised in a manner to indicate that there is increased combustion of carbohydrate. It seemed likely that stimulation of the same processes in the normal animal under insulin must be responsible for the disappearance of glucose from the blood. But the experimental evidence goes to show that the mechanism of action is much more complex. Glycogen is certainly not formed when insulin is given to normal animals (McCormick, Macleod, O'Brien, and E. C. Noble); indeed, it is decreased in amount[3] (Dudley and Marriam), and no certain evidence can be obtained from respiratory experiments that more active combustion of glucose is a necessary accompaniment of the lowering of blood-sugar. The consumption of oxygen greatly increases in dogs preceding the onset of symptoms, and the respiratory quotient usually becomes somewhat raised (Dixon, Eadie, Macleod, and Pember), but in mice changes of an opposite character occur (Dudley, Laidlaw, Trevan, and Boock), and in rabbits they are at first like those in dogs, though less marked, and subsequently like those in mice. The glucose which disappears is apparently neither oxidised to carbon dioxide and water nor polymerised into glycogen. For the present the problem is unsolved, but we must not lose sight of the possibility that insulin changes both glucose and glycogen into some intermediary product which we fail to identity with our present methods of analysis either because it does not give the reducing reactions upon which the detection and estimation of sugars depend, or because it is not precipitated by alcohol after treatment with strong alkali, which is the characteristic property of glycogen. That such substances may exist in the tissues is indicated by the fact that it is impossible after injecting large amounts of sugar into animals to recover much more than one-half by chemical analysis of the entire body.

Acts in the Tissues, not in the Blood.

Whatever may be the nature of the mechanism by which the blood-sugar becomes lowered there is no doubt that it acts in the tissues and not in the blood itself (Eadie and Macleod). Thus, the addition of insulin to blood incubated outside the body does not alter the rate at which the sugar disappears from it, and when the isolated heart is perfused with a suitable saline solution containing sugar the addition of insulin to the solution causes this to lose its sugar more rapidly (Hepburn and Latchford).

The hypoglycæmic effect of insulin lasts for a period which varies in different animals. In rabbits the blood-sugar often begins to rise again in about an hour after the injection, but this depends very largely on the amount of glycogen which is stored in the liver. This becomes converted into glucose to replace that lost from the blood, so that well-fed animals show much quicker recovery, and can withstand much larger doses of insulin, without the development of symptoms, than those previously starved. This mobilisation of the carbohydrate reserves would appear to depend on the transmission to the liver through its nerve-supply of messages set up by the hypoglycæmic condition, for Burn has shown that if the nerve pathway (splanchnic) be blocked by the drug ergotonine, insulin causes in well-fed animals more profound a degree of hypoglycæmia than otherwise. The importance of the glycogen reserves in combating the hypoglycæmic effects of insulin warns us that we must be careful in giving it to diabetic patients in whom, as we have seen, these are abnormally low.

OTHER PHYSIOLOGICAL PROBLEMS.

Numerous other problems relating to the physiological action of insulin are being investigated, but time will not permit of more than a brief allusion to one or two of them. One is its effect on hyperglycæmia due to other causes than removal of the pancreas. These include administration of glucose either by mouth or parenterally—exogenous hyperglycæmia we may call it—and increased production of glucose from the glycogen stores of the liver—endogenous hyperglycæmia. This increased breakdown of glycogen may be brought about by a variety of experimental conditions which are conveniently classified as nervous and asphyxial. Under the former category are included puncture of the floor of the fourth ventricle of the medulla and stimulation of the sympathetic nerve-supply of the liver, either electrically or by the injection of epinephrin; and under the latter, besides the various forms of asphyxia itself, the effect of numerous drugs such as the anæsthetics. So far as it has been investigated insulin is capable of preventing the development of hyperglycæmia in all these conditions. Most attention has been paid to its effect on the hyperglycæmia due to epinephrin, partly because of the possibility that insulin may be assayed by determining the amount necessary to antidote a known amount of epinephrin, which itself can be accurately assayed, and partly because an investigation of the physiological antagonism between these two hormones may throw some light on the mechanism of the action of insulin. Let me give one example to illustrate. We have seen that insulin causes the glycogen stored in the liver to become less in amount, acting in this regard like epinephrin, although probably much less quickly. When insulin is given along with epinephrin, however, glycogen disappears from the liver much more slowly than with epinephrin alone, indicating that under certain conditions the pancreatic hormone arrests rather than stimulates the breakdown of glycogen (E. C. Noble). When these two hormones are in excess in the body the one prevents the other from causing glycogen to disappear. Another curious result of a somewhat similar nature has been obtained by Burn with pituitrin, a hormone derived from the pituitary gland. When it is given along with epinephrin it prevents hyperglycæmia, and when it is given with insulin it prevents hypoglycæmia. I have mentioned these results to indicate the very puzzling nature of the problem of the action of insulin and to show that this action may possibly be linked with that of other hormones in the animal.

---

[3] This disposes once and for all of the suggestion that the hypoglycæmia is due to a shutting-down of the production of glucose from the liver, which is further confirmed by the observation of Mann and Magath that insulin has its usual hypoglycæmic effect after removal of the liver.

Another interesting effect of insulin is on the peculiar form of experimental diabetes caused by the drug phloridzin. Glycosuria occurs without there being any increase in the blood-sugar and the oxidation of carbohydrate becomes interfered with, as revealed by a failure of the respiratory quotient to respond to the ingestion of sugar. Now, it is significant, as S. U. Page has found, that when insulin is given along with sugar to dogs completely under the influence of phloridzin the respiratory quotient becomes decidedly raised and the glycosuria lessened.

Whatever the mechanism of the action of insulin may be, it is important to bear in mind that the direction of its control of carbohydrate metabolism is apparently not the same in the diabetic as it is in the normal animal, for in the former it causes increased formation of glycogen and greater combustion of glucose, whereas in the latter it inhibits the former process, if not indeed exciting glycogenolysis, and it does not necessarily stimulate the combustion of glucose. Where there has been a deficiency of insulin for the physiological control of carbohydrate metabolism, as in the diabetic, its replacement, by injection, causes those intermediary products of carbohydrate metabolism which have accumulated in the body because of its absence to be immediately transformed. Insulin oils the halting machinery of carbohydrate metabolism in diabetes and allows it to run smoothly again, but it interferes with the action of this machinery when it is given to a normal animal in whom there is already a sufficient supply of it for all physiological purposes.

CHEMICAL NATURE OF INSULIN.

Little is as yet known regarding the chemical nature of insulin. Many of its reactions are similar to those given by proteose, an early digestive product of protein. This probably explains why it is so readily destroyed by the ferments of the pancreas and stomach and cannot be successfully given by mouth. In the purest preparation from ox pancreas all of the characteristic colour reactions of protein are absent except the biuret reaction. It contains no phosphorus or carbohydrate but a large percentage of sulphur. This would seem to indicate that it must be some low form of protein, although it is possible that it may not belong to this class of bodies at all but be some simpler substance with protein derivatives attached to it as impurities. In this connexion it is significant that very active insulin has been prepared from the pancreas of the skate in which the biuret test could not be obtained. With regard to its solubilities, upon which, of course, its isolation depends, neutral alcohol up to about 80 per cent. dissolves it, so also does water, but it is precipitated in very weak acid (pH 4–6), and in the presence of high concentration of neutral salts. It is also precipitated by such reagents as picric and benzoic acids and it forms a salt with hydrochloric acid. The Collip process for its isolation in a state of sufficient purity for clinical use depends on dissolving it out of the macerated pancreas by weak (60 per cent.) alcohol, evaporating the extract to small bulk in vacuo, removing foreign proteins by stronger alcohol (80 per cent.), and fats by centrifuging or by ether, and finally precipitating the insulin by increasing the alcohol to 90–92 per cent. Further purification can then be effected by re-precipitating either by very weak alkali (Shaffer-Doisy method) or by means of picric acid (Dudley method). In faintly acid reaction it withstands heat, for example, such a solution can be continuously boiled for over an hour without perceptible deterioration, but in faintly alkaline reaction heat soon destroys it. It does not dialyse in faintly acid reaction in which also it is readily adsorbed by charcoal and kaolin. These facts are sufficient to show that insulin is a substance of complex chemical structure, which indicates that its isolation in a chemically pure state will be a matter of great difficulty. Its preparation by synthetic means is therefore at present out of the question.

Finally, let me say a word concerning the insulin-like substances which have been prepared by Collip's process from numerous sources such as yeast and fungi. Most of these differ from insulin prepared from the pancreas of mammals or from the principal islets of the bony fishes in that they only slowly reduce the blood-sugar; indeed, this effect may be delayed for a day or so. The possibility therefore exists that they merely act by stimulating the production of insulin from the pancreas, and if this be the case they can scarcely be of much value in the treatment of diabetes.

BACTERIAL INFECTION OF THE URINARY TRACT IN INFANCY AND CHILDHOOD.*

BY E. BELLINGHAM SMITH, M.D.,
M.R.C.P. LOND.,
PHYSICIAN, ST. GEORGE'S HOSPITAL; PHYSICIAN, ROYAL NORTHERN AND QUEEN'S HOSPITAL FOR CHILDREN, LONDON.

BACTERIAL infection of the urine occurs from earliest infancy throughout childhood, and cases presenting such infection must appear to all of you general practitioners at some time or other. My own experience is that, owing to the variety of symptoms which arise, that it frequently goes undiagnosed or is mistaken for a number of other complaints. The urine of infants and children may be the habitat of various bacteria, amongst which I may mention the staphylococci, streptococci, *B. coli*, *B. typhosus*, *B. proteus*, *B. pyocyaneus*, *B. tuberculosis*, and *B. diphtheriæ*. Of the diseases associated with these bacteria, typhoid is becoming rare in this country, and in only a small percentage of cases is *B. typhosus* recovered from the urine. Similarly, while certain types of tuberculosis are common in childhood, an infection of the urinary tract alone is rarely seen. Of all these infections by far the most common is that by *B. coli* alone, or in conjunction with the staphylococcal or streptococcal group.

Apart from infections where an organism can be isolated, we have that large group of nephritis cases, some of which follow the specific fevers, such as scarlet fever and pneumonia, or are syphilitic in origin, and a still greater number, so-called idiopathic, all of which are admittedly infective, but in the greater number of which it has as yet been impossible to isolate the causal agent. The infective nature of the last group, which at one time we were willing to attribute to chill, is well shown by the following experience I had recently when I was asked to see a family of three small boys, all of whom had nephritis. There was no antecedent history of any infectious illness or sore throat; the second boy was taken ill five days after the first, the third some seven days later. In each case there was acute nephritis with hæmaturia, albuminuria, and casts. Cultivation, however, of a sterile specimen of urine yielded no results, despite the apparent infectivity of this disease from one child to another. I do not propose to deal any further with this class of uncertain origin, but will confine my remarks to that in which it is possible to isolate an offending organism. And of these organisms I propose only to deal with the *B. coli* alone or in conjunction with the staphylococci or streptococci.

---

* A paper read before the Lincoln Medical Society.

Infection of the urine by the *B. coli*, staphylococci, and streptococci occurs either as a primary disorder or as a complication in some other general systemic infection, as a sequel of diarrhœa and vomiting or chronic constipation, as a secondary infection in congenital malformations of the kidneys, or with renal or bladder calculi, in meningeal states, and in cases where there has been immobilisation in plaster for a long period for spinal and hip disease. Finally, it must be remembered that any of these organisms may be present in the urine without there being, of necessity, any corresponding signs of inflammation of the urinary tract or any disturbance of health. We have then to consider this condition under these headings: (1) Bacterial infections without pathological changes in the urine, stone, or complicating other diseases; (2) bacterial infections, a primary disorder, with pathological changes in the urine; (3) bacterial infections, complicating other diseases and giving rise as well to pathological changes in the urinary tract.

Bacterial Infections without Pathological Change in the Urine.

Cases falling under this heading are of three classes: (*a*) those infants and children who at one time have had a definite acute infection but have since developed an immunity to their infection without actually freeing their urinary tract from the invading organism; (*b*) infants and children possibly possessing a natural immunity to the organism in question; and (*c*) cases in which the organism present is merely a terminal infection in the cause of some other fatal disorder.

These three classes require little explanation. Of the first I shall have something further to say under the heading of prognosis. The second should be clear to the understanding when we compare such a state with other systems of the body. For instance, pneumococci and other organisms abound in the respiratory tract, but we are fortunately not all of us the subjects of pneumonia. In like way the presence of *B. coli* in the urine does not necessarily foretell a certain pyelitis or pyelonephritis unless the resistance and natural immunity is lowered by some extraneous cause. Possibly to this type belong a limited number of cases of enuresis. Hyperacidity of the urine has been instanced as a cause of incontinence in childhood, and a highly acid state of the urine is a concomitant of *B. coli* infection; moreover, in a few such cases with enuresis *B. coli* has been isolated in limited numbers without there being any evidence of inflammatory changes in the urinary tract. Under the third type we have cases where, in a prolonged or fatally terminating illness, a routine examination of the urine reveals *B. coli* or cocci without evidence of pus cells or albumin; such cases, as one would expect, occur more frequently amongst girls than boys, and should be looked upon as a direct contamination of the content of the bladder by soiling of the vulva by fæces, while the child is unconscious and incontinent. The only important point in these cases is not to overlook the primary diagnosis or confuse it with a real *B. coli* infection.

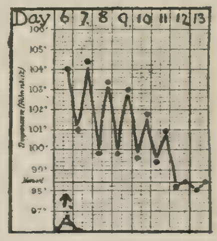
Bacterial Infection with Pathological Changes in the Urine.

We now come to the second heading—*B. coli* infection as a primary disorder with evidence of inflammation and pathological changes in the urine. Theoretically we can divide this group into three subdivisions according as the symptoms denote: (1) a bladder infection or cystitis; (2) a pyelitis or inflammation of the pelvis; (3) a nephritis or inflammation of the kidney substance, which in extreme cases may be suppurative. In practice, however, any two or all three may be equally or to a lesser degree affected at one and the same time. On the whole, the symptoms will vary as to which portion of the urinary system is to the greatest degree involved. Thus, where the bladder is attacked, we have frequent and painful micturition; the urine is cloudy and foul-smelling, and contains quantities of pus and albumin, and occasionally blood. In such cases there may be a mixed infection with staphylococci or streptococci. Pyrexia, on the whole, is absent or only slight. The constitutional symptoms apart from the urinary discomfort are, as a rule, negligible.

In pyelitis, on the other hand, there is, as a rule, distinct constitutional upset. And it is this type of case which frequently goes undiagnosed or wrongly diagnosed.

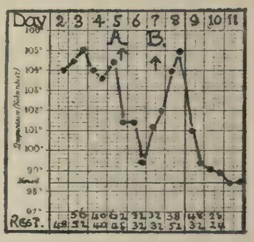
In infancy the onset of the disease is often insidious and is marked by general malaise, anorexia, fretfulness, irritability, pallor of an earthy type, and a rise of temperature, or daily rises of temperature associated with shivering or definite rigors. Such rigors are almost pathognomonic of *B. coli* pyelitis. Dysuria and incontinence or frequency are difficult to determine in young infants, and if present are usually not very marked symptoms, so that the direct relation of the illness to a urinary infection is not always apparent. In older children the onset may be sudden with vomiting, acute abdominal pain, high temperature, and in both infants and children a markedly increased respiratory rate. Frequency of micturition or some dysuria may or may not be present. Frequently the child is drowsy with face flushed, eyes bright, and manner apathetic, suggesting typhoid. In others the increased respiration gives rise to a suspicion of pneumonia. In a third type the mental aspect—drowsiness and sometimes in severe cases, head retraction, delirium, and other symptoms of meningismus—give rise to a suspicion of meningitis. There may be tenderness in one or other loin and, if the pain persists, some enlargement of kidney may be felt; otherwise the condition suggests an acute appendicitis. In infancy the attack may be heralded by some upset of the bowels, such as diarrhœa. In older children constipation before or during the attack is of common occurrence. In two cases of this disease I have noted some enlargement of the spleen suggestive of a systemic infection, and in infants some general bronchitis or even a supervening broncho-pneumonia is not uncommon.

CHART 1 (CASE 1).



A = Date of identification of *B. coli* infection and administration of alkalies (pot. cit., 10 gr., four-hourly).

CHART 2 (CASE 2).



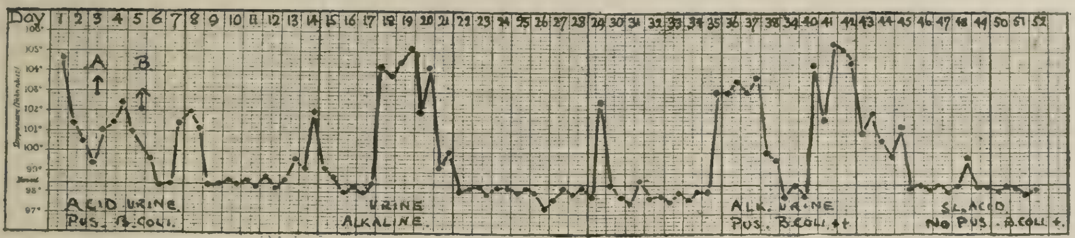
A = Diagnosis corrected to *B. coli* pyelitis; alkalies commenced. B = Dose of alkali doubled.

CASE 1.—A girl, aged 6 years, admitted with five days' history of pain in left side of abdomen, frequency of micturition, drowsiness, constipation, and fever; urine intensely acid, containing a trace of albumin, a quantity of pus, and *B. coli*. The chart exemplifies the continued fever type of the disease, abated on the eleventh day by administration of alkalies. Diagnosis: acute pyelitis. Recovery complete (Chart 1).

CASE 2.—A female infant, aged 10 months, admitted with cough, vomiting, and diarrhœa. On admission face flushed, respiration rapid, high temperature. Provisional diagnosis: pneumonia, which was rapidly disproved by complete freedom of lungs from physical signs and presence of albumin, pus, and *B. coli* in large numbers in the urine. Rapid recovery on alkaline treatment. Chart 2 illustrates confusion of disease with pneumonic states and shows rapid defervescence of temperature when large doses of alkalies (pot. cit. 30 gr., sod. bicarb. 20 gr.) were administered.

CASE 4.—Girl, aged 7½ years, admitted semi-conscious and delirious, with great mental irritability, and incontinence of urine and fæces. Tache cérébrale well marked, Kernig's sign, onset sudden. Sent to hospital as meningitis. Previous history of enuresis for two years, following a severe attack of whooping-cough. Urine acid, trace of albumin, pus cells, and *B. coli* in profusion. Chart 3 shows persistent recurrent fever in spite of treatment, and exacerbations whether urine is acid or alkaline. After ten weeks in hospital the child was discharged with urine free from pus and albumin, but *B. coli* were still present on cultivation. Two months later she was again readmitted with a recurrence of all symptoms and pus in the urine. The previous enuresis suggests a latent and long untreated chronic infection.

CHART 3 (CASE 4).



A = Alkali, 30 gr., six-hourly. B = 60 gr., four-hourly.

CASE 6.—Boy, aged 1 year, admitted with pneumonia. In the course of convalescence he developed a high temperature with rigors. Urine found to contain pus, albumin, *B. coli communis*, and *Staphylococcus aureus* and *albus* in large numbers. Complete recovery with alkalies.

The temperature chart in this disease is worthy of some further consideration. A series of charts herewith illustrate different types of the disease. In certain cases the disease may be apyrexical throughout, in others the fever is high and maintained, as in typhoid or pneumonia; in others the charts are distinctive of the disease, as in the "malarial" type, with signs which occur in infancy (Chart 6) or in the recurrent type of fever which is prevalent in the more chronic relapsing cases in older childhood (Chart 4). There is not one showing a condition of long-continued fever, but it is quite easy to imagine that such might be the case in at least one of these, if treatment had not abated the infection (vide Charts 1 and 2). The urine in both infancy and childhood in these cases of pyelitis is highly acid, contains a small quantity of albumin, a variable number of pus cells, and a profusion of organisms which exhibit the morphological and cultural features of *B. coli*.

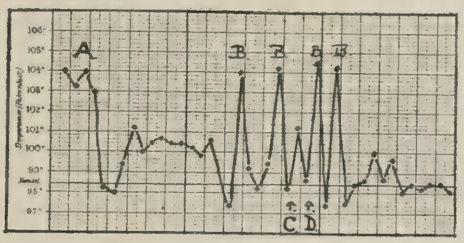
Evidence of infection of the kidney by *B. coli* is shown in some cases by profuse hæmaturia; in others the picture is identical with that of acute idiopathic nephritis; the urine being smoky, containing blood, pus, albumin, and rarely a few casts, and culturally *B. coli*. There may be some œdema and pallor in these cases, but more frequently there is no œdema and no evidence of anæmia. In a few rare instances suppuration occurs in the substance of the cortex of the kidney. These cases are fatal. In the only one I remember to have seen the symptoms were pallor, semiconsciousness, gradually increasing to coma and death. A diagnosis of meningitis had been made, but an examination of the cerebro-spinal fluid yielded neither any cellular increase nor pathogenic organism, while the urine showed pus cells and *B. coli*. Post mortem a number of small yellow abscesses were visible in the cortex. Such is a brief clinical picture of *B. coli* infection of the urine in infancy and childhood.

Bacterial Infections Complicating Other Diseases and also Giving Rise to Pathological Changes in the Urinary Tract.

We now come to our third group—namely, *B. coli* infection grafted on to some other disorder as a complication. While the diagnosis of a primary *B. coli* infection is not always easy, the addition of such to some other fever or disease often produces a most bewildering and confusing picture, and it should be remembered that the incidence of this disease during the course of other illnesses is no rare occurrence. Conditions which (1) lower the general resistance, or (2) in any way implicate the gastro-intestinal tract or cause abrasion of the latter, appear to facilitate the passage of *B. coli* from its intestinal residence to a fresh area in the urinary tract. Thus, on the one hand, we see it complicating the termination of an attack of pneumonia, as in Chart 6, and on the other the convalescence of typhoid. Whenever it happens the symptoms already mentioned follow or are merged with those of the original infection.

Probably the greatest difficulty will arise where a *B. coli* infection is implanted on some other kidney trouble or some malformation of the kidney. Recently I was asked to see an infant who had failed to gain in weight and suffered from recurrent attacks of diarrhœa and sickness, despite the most careful feeding. A temperature chart showed recurrent attacks of fever, not always coincident with the intestinal derangements, and in two of these attacks there had been definite rigors. Examination of the urine showed pus cells and *B. coli* and a trace of albumin; the child was of the usual pallid, fretful type which one associates with a prolonged *B. coli* infection, and as a consequence a diagnosis of pyelitis was made with some assurance and hope of successful recovery. Three or four weeks later, however, the child died in a state of uræmic convulsions, and post mortem we found double congenital hydronephrosis with a superadded *B. coli* infection.

CHART 4 (CASE 6).



A = Crisis of pneumonia. B = Rigor. C = Date of identification of *B. coli* infection. D = Beginning of alkali treatment.

Prognosis.

The next question that arises is, What is the ordinary progress of this disease and of what nature is the prognosis?

Cases of *B. coli* infection fall roughly into four groups: (1) Those having an initial acute attack which reacts to treatment with complete subsidence of symptoms and freedom from *B. coli* in the urine.

(2) Cases which recover from their initial attack, but though devoid of fever and constitutional symptoms continue to show the presence of *B. coli* in the urine. Such cases are liable to relapse and present acute symptoms again on any deterioration of health reducing their acquired immunity. (3) A recurrent chronic type, not reacting to treatment and not developing any immunity. Such cases drag on for months and years with variable periods of ill and good health. 4. Fatal cases, which are rare. In these there is, as we have already pointed out, renal suppuration. Such cases are resistant to treatment and gradually sink and die uræmic.

The prognosis in this disease depends, as in most medical disorders, on early diagnosis and efficient treatment. Delay in either one or the other tends to chronicity; once well implanted, this infection is exceedingly difficult to eradicate.

Treatment.

Treatment resolves itself into :—

1. Rest in bed.
2. Liquid diet with plenty of bland fluids.
3. Attention to the bowels. Correction of constipation, the arrest of any diarrhœa or morbid processes in the bowel, and the administration in any case of some regular intestinal antiseptic.
4. The exhibition of drugs, of which by far the most valuable are simple alkalies, such as pot. cit., sod. cit., or sod. bicarb. These must be administered in large doses; 10 to 15 gr. of the former can be safely given every two hours to an infant of 1 year for a short period, and then given four-hourly and six-hourly until all pus and *B. coli* have disappeared, or mixtures of pot. cit. and sod. bicarb. may be used. Continuation of this treatment is generally recommended until all constitutional symptoms have subsided and the urine is alkaline. Now I would state that subsidence of constitutional symptoms does not imply freedom from *B. coli* infection, and that alkalinity of the urine cannot always be attained, even with very large doses of alkalies by mouth—and that, moreover, despite alkalinity of the urine attacks of fever and recrudescences of the disease may still occur. The only real indication of cure is the absence of pus and micro-organisms from the urine. These points are well illustrated in the charts (see Chart 4). Occasionally large doses of alkalies are ill borne, and continued administration unquestionably in many cases produces lack of appetite, general depression, and even vomiting. They should, however, be pressed to the limit of tolerance, and may then be superseded by some urinary antiseptic, such as helmitol or urotropin. I have never seen any real benefit accrue from the use of these substances alone in this disease, except in the case of mixed infections. However, the alternative use of these drugs and alkalies seems at present the best procedure when the disease is protracted in its course.
5. Treatment by autogenous vaccines. With regard to this method, I have personally had very little success. In a few cases I have even believed I have seen harm done, and in the type of case, the chronic recurrent, where one most desires assistance, it has in my hands proved useless.

The question of mechanical interference, such as lavage of the bladder, is one to be carefully considered. In mixed infections this is possibly of value, but in the great bulk of cases and in all pure *B. coli* infections, instrumental treatment should be avoided. Whatever method of treatment is employed, every effort should be made to see that the urine is free from *B. coli* before such treatment and observation is discontinued. Many chronic cases, I am confident, arise from neglect of this simple precaution.

Diagnosis.

The diagnosis of this condition has been to some extent reviewed in discussing the symptoms to which it gives rise. Acute cystitis, due to the *B. coli* alone or to mixed infection of *B. coli* and streptococci, is generally readily recognised by the dysuria and frequency to which it gives rise, and the nature of the infection is readily discovered by microscopical examination of a catheter specimen of urine. Acute pyelitis, however, may give rise to some difficulty unless it is always remembered that unexplained fever in infancy or childhood may have its origin in a *B. coli* infection of the urinary tract. In many of these cases, as I have pointed out, there are few occasions in which the symptoms indicate irritation or inflammation of the pelvis or kidney itself. Where there is acute hæmaturia I have seen the diagnosis of stone made, or rarer conditions such as essential hæmaturia or scurvy, where a simple cultivation of the urine would have shown *B. coli.*

Acute cases with abdominal pain and fever and rapid pulse suggest appendicitis. Continued fever with some drowsiness and irritability suggest typhoid, general tuberculosis, or meningeal conditions. The same with increased respiration, so often seen in this disease, suggests a pneumonia, and I have no doubt that the diagnosis of deep-seated pneumonia is not infrequently made in this disease. A small apical pneumonia and this condition are easily confused, but a strict examination will reveal the first and a catheter specimen of urine the second. Where this condition complicates a pneumonia or arises in convalescence the most natural assumption is to attribute the fever to some empyema formation or an acute otitis media. In Case 6 the patient's chest was explored on more than one occasion on these grounds. Where there are rigors infective endocarditis or septic conditions may be inferred wrongly. The close similarity of the chart to malaria must be confusing in countries where that disease is endemic.

Where the fever is recurrent suspicion will arise of tuberculosis; glandular tuberculosis of the abdomen not infrequently presents a picture with this characteristic chart. Rheumatic and nervous children are liable to slight recurring bouts of fever without any very definite physical signs. Tonsillitis in deep-hidden tonsils gives rise to recurrent attacks of febrile disturbance with general malaise.

The mode of entrance of these various organisms, and in especial the *B. coli*, has aroused a certain amount of controversy. The old view was that in all cases infection was of an ascending nature via bladder and ureter to the kidney. The extreme prevalence of this disease in female infants and children was quoted as a proof of this method of ingress. On the other hand, although less common in males, it does occur in that sex, and direct invasion per urethram seems difficult of comprehension on anatomical grounds. Then it was stated that invasion along the ureter against the urinary flow was impossible; this, however, has been proved possible by experiment. It may be assumed, therefore, that in certain cases infection of the bladder at all events may take place from soiling of the vulva by fæces in young children, and it is possible that a secondary infection of the pelvis and kidney results, therefore, by direct spread, such spread being facilitated by possible inflammation of the bladder, obstruction of the ureteric orifice, and stagnation of urine in the ureter.

There are, however, a number of cases in which the predominant and apparently sole lesion is one of pyelitis or pyelonephritis; from these it has been assumed that there is a blood infection, the organism entering the blood-stream and selecting the kidney as its victim, owing presumably to some lowering of resistance of that organ. The general septicæmic state of some of these little patients and its close resemblance under certain conditions to an allied condition, typhoid, suggests that the blood-stream, therefore, is also a path of infection.

Lastly, we have the lymphatic theory of spread of infection; one path being by way of the lymphatics of ureter from the bladder to the kidney, and secondly, directly from the lymphatics of the large bowel to the lymphatics of the capsule of the kidney.

PULMONARY AMŒBIASIS.

BY PHILIP MANSON-BAHR, *D.S.O.*, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES AND ALBERT DOCK HOSPITAL; LECTURER, LONDON SCHOOL OF TROPICAL MEDICINE.

IN most cases amœbic infection of the lung is due to direct extension of a previously existing hepatic abscess through the diaphragm. Cases of this nature are well known, but their recognition at any early stage after rupture is necessary in order that specific and efficient treatment may be immediately installed. Abscess of the lung due to *Entamœba histolytica* can occur quite independently of abscess of the liver, though seldom recognised during the lifetime of the patient. It is with this aspect of pulmonary amœbiasis that I mainly wish to deal in the present paper.

In the older literature in the case recorded by Colin[1] in 1873, ten abscesses of the lung had arisen secondary to a thrombus in the liver, and in another reported by Moxon[1] the liver abscess had actually burst into a sub-hepatic vein, and thus spread to the lung. In this first condition, which may be termed primary pulmonary amœbiasis, the route by which the entamœbæ gain the pulmonary circulation is probably the one described by Bunting[2] (1906)—that is, by direct embolism through the circulation from the colon. In this case firm consolidated nodules were found in the lung in which entamœbæ were demonstrated in section. In another described by Opie[3] in 1901 a large amœbic abscess was found in the right lung, together with an evidently healed amœbic abscess of the liver. Tuffier[4] in his paper evidently recognised the condition during life, and the patient is reported to have been cured by operative interference. In this case the abscess was present in the right lung; hæmoptysis, fever, and other symptoms were present, but no assistance could be obtained from radiography in arriving at a diagnosis. Loison[5] reported a similar instance and suggested aspiration of the pus, the point of the needle being directed visually through a radioscopic screen, which in a radiographic report by Herold[6] seems actually to have been accomplished, for in the figure reproduced the outline of the abscess can be quite clearly seen below the angle of the right scapula. In this instance hæmoptysis was present and bodies were found in the sputum which resembled degenerate entamœbæ. The patient subsequently developed an hepatic abscess. Simonin[7] reports an autopsy in which two abscesses were situated in the right lung, quite separate and independent from three abscesses in the liver. Macfie[8] in Accra also has found amœbic abscess of the lung associated with a similar condition of the liver at autopsy. Quite recently Ramond,[9] Denoyelle, and Lautman have recorded an interesting case where multiple pulmonary abscesses without ascertainable involvement of the liver were recognised during life and where all symptoms disappeared after exhibition of emetine.

Primary Pulmonary Amœbiasis.

Three striking instances of what appear to be primary pulmonary amœbiasis caused by infiltration of the lung by *E. histolytica*, quite independent of liver abscess, have recently been met with in hospital practice. All three cases have responded in a dramatic and striking manner to emetine therapy.

CASE 1.—An ex-soldier had served in India during the war and had suffered from dysentery in 1918, with subsequent relapses treated with emetine (presumably amœbic in origin) was admitted into hospital on March 12th, 1921. He was then complaining of intermittent pain, acute at times, in the lower chest on the right side. For the last 14 days he had been troubled with cough, accompanied by fever and some respiratory distress; the number of respirations averaged 26–28 per minute. The sputum was profuse and purulent in character, but there had been no hæmoptysis. The patient was evidently ill, pallid, and emaciated, weighing 112 lb. Pyrexia was intermittent, varying between 101° and 102° F.; nocturnal perspiration was profuse. No clubbing of the fingers was noted, or any "shoulder pains."

At first hepatic abscess was suspected, as the patient had suffered from dysentery and there was a leucocytosis of 14,000; however, the fæces were frequently microscopically examined for *E. histolytica* cysts with a negative result. There did not appear to be any special involvement of the liver. In fact, the pain was situated above the hepatic area and pulmonary signs were sufficiently apparent. There was a patch of dullness to percussion, some 4 inches in diameter, below the angle of the right scapula when the breath sounds were bronchial and an occasional expiratory crepitation could be distinguished. Similar, but smaller, broncho-pneumonic areas became apparent from time to time after frequent examination at the lower lobe of the left lung. The sputum, which contained numerous pus and large epithelioid cells, was frequently examined for tubercle bacilli without avail.

In view of the possible involvement of the liver, the organ was aspirated without result; no improvement in the pulmonary signs were noted, and the pyrexia remained the same as before. The diagnosis then varied between a simple or tuberculous broncho-pneumonia and the consensus of opinion was in favour of the latter, and one month after admission and six weeks after the commencement his condition had become steadily worse. Purely on empirical grounds and the possibility of amœbic involvement of the lung, emetine injection (1 gr.), together with pulv ipecac. 10 gr., were commenced on April 11th, 1921. An immediate and striking improvement was noted (Chart 1); the pyrexia, which had persisted for the previous six weeks, resolved in four days; the broncho-pneumonic signs disappeared and the patient's general condition improved to such an extent that he was discharged on May 18th in apparent good health. He received altogether 260 gr. of pulv. ipecac. During the course of his acute illness he had become emaciated, and he rapidly regained weight up to 140 lb.—an increase of 28 lb.

CASE 2.—An ex-soldier, who had served in Mesopotamia, was admitted on May 10th, 1921, shortly after the discharge of the first case. He also had suffered from dysentery contracted in 1919 and had experienced numerous relapses, for which he had been treated with emetine. In August, 1920, during one of these relapses, he was admitted to the Hospital for Tropical Diseases with clinical signs of dysentery, and for which he was treated with emetine bismuthous iodide. No entamœbæ were found in the fæces, but the sigmoidoscopic appearances were characteristic of amœbic infection.

A fortnight after admission he commenced to suffer from pyrexial attacks with "shivering fits," broncho-pneumonic symptoms, nocturnal perspirations, profuse purulent expectoration, but again no hæmoptysis. Respiratory distress was evident and the number of respirations averaged 24 per minute. The patient's general condition was decidedly poor, perspiration was profuse and evident, emaciation extreme (weight 114 lb.), skin tense and dry, and the general condition of the patient and the remittent pyrexia (T. 102° to 103° F.) certainly suggested at first sight miliary tuberculosis. On examination numerous crepitations and fine sibilant rhonchi were apparent evenly diffused over both lungs. By light percussion small scattered and indefinite patches of dullness could be distinguished, but there was nothing to suggest any involvement of the liver. There was a slight leucocytosis of 9000; the fæces contained no *E. histolytica* cysts; the sputum numerous pus and epithelioid cells, but no entamœbæ (which were specially looked for).

Some three weeks after admission the general condition of the patient was worse, and the suggestion of miliary tuberculosis seemed to receive support. At this time definite rigors were noted, the temperature rising suddenly with profuse perspirations to 104° F. Two of these rigors occurred during a space of five days.

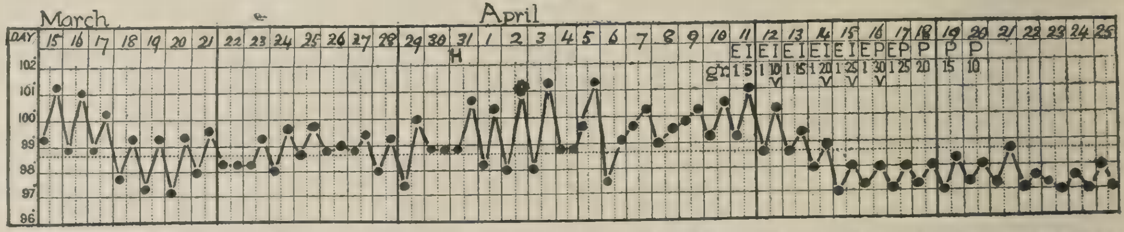
In view of the case already recorded, emetine injections were instituted, with immediate improvement in the clinical signs and in the patient's condition, as the chart shows (Chart 2). He received in all 16 gr. of emetine, followed by 300 gr. of ipecacuanha spread out in doses of 10 gr. each nightly. The improvement in the condition of the patient was so striking as to be apparent to all. His weight increased by 21 lb., and he was discharged on July 26th, 1921, in apparent perfect health. He has suffered from one similar relapse since, for he was readmitted a year later with similar but milder symptoms, which once more speedily yielded to emetine and ipecacuanha therapy.

CASE 3.—A lascar, aged 28, was admitted to the Albert Dock Hospital with a provisional diagnosis of broncho-pneumonia. As the chart indicates (Chart 3) he was in a very distressed condition—temperature 103° F. with orthopnœa, marked dyspnœa, and respiratory distress. The pulmonary signs were most evident at the right base, where a distinct friction rub, bronchial breathing, and crepitations indicated a consolidation of the lung. Within a few days similar signs were audible also on the opposite side. The sputum, which was abundant, purulent, frothy, and streaked with blood, contained pus and epithelioid cells, scanty pneumococci, but no T.B.

The patient's evident anæmia could be attributed to a concomitant ankylostome injection as the ova were present in the fæces. A high leucocytosis of 94,000 was present, and this figure seemed to indicate that in this case one was not dealing with either a tuberculous broncho-pneumonia or the usual type of broncho-pneumonia commonly encountered in this class of patient. There was slight thickening of the consolidated broncho-pneumonic nodules, I do not believe this to be possible. No assistance was obtained in aiming at a diagnosis by the X rays.

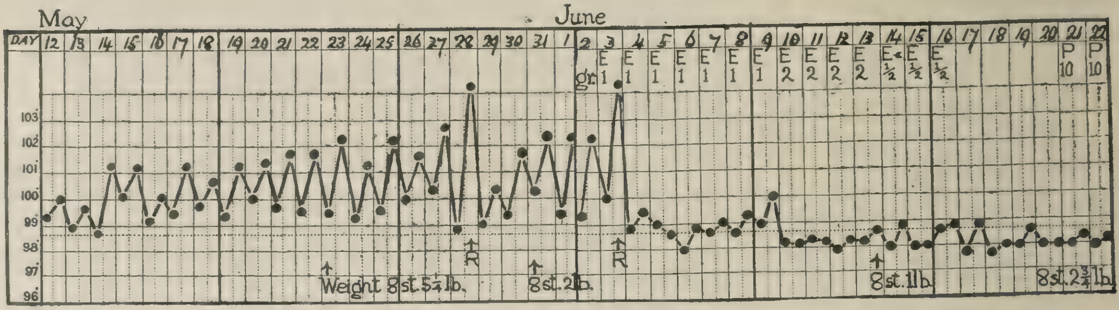
My object in publishing this paper is to bring these facts to the notice of tropical workers, as probably these cases are of more frequent occurrence than has been thought to be the case. It is possible that many of the obscure unresolving broncho-pneumonias in natives which one encounters in hospital practice, especially amongst lascars, are really of this nature.

Chart 1.



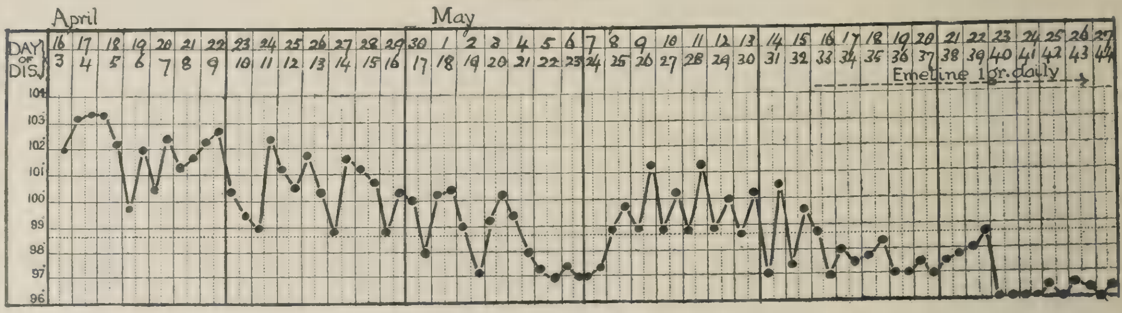
Case 1.—Showing resolution of pyrexia in four days after injection of emetine. H = hypodermic injection of influenza vaccine. E = emetine. I = ipecacuanha. P = pil-ipecac. V = vomiting.

Chart 2.



Case 2.—Another illustration of immediate improvement after institution of emetine treatment. R = rigor.

Chart 3.



Case 3.—A third striking example of the beneficial effect of emetine injections. The patient was previously in a very distressed condition.

sigmoid colon, but otherwise no evidence of a recent amœbic infection.

At the end of the third week in hospital, when treated on empirical lines, the condition had not in any way improved, and signs of a patchy pneumonic consolidation were present throughout both lungs; it was then decided to try the therapeutic effect of emetine (Chart 3), with instantaneous and striking effect. The results of this treatment (emetine 11 gr.), followed by a course of pulv. ipecac. 5 gr. daily for 14 days, appear to have been permanent. On July 7th he returned to his ship in good physical condition, having gained over 28 lb. in weight.

The diagnosis in these cases was arrived at by a process of exclusion, by their previous history of amœbic infection, by the marked leucocytosis, and by observing the instantaneous and almost miraculous effect of emetine therapy.

From an ætiological standpoint it would have been more satisfactory to have found *E. histolytica* in the sputum, but from the nature of the lesions, which probably, as in Bunting's case,[2] are composed of

Pulmonary Amœbiasis Secondary to Liver Abscess.

The bursting of an unrecognised liver abscess into the lung may produce the most varied pulmonary signs, and it is not surprising, when such an accident occurs, that the physician is led to diagnose various pneumonic conditions, such as bronchiectasis, tuberculosis, or unresolving pneumonia. It may happen that the original hepatic abscess produced no symptoms whatever, and therefore remained unrecognised till the rupture had taken place.

Case 4.—A regular soldier, a staff-sergeant in the R.F.A., first went to India in 1909. In December, 1914, he became ill with dysenteric symptoms, and phlebitis of both legs. Later he is said to have suffered from pneumonia, but the liver was aspirated under an anæsthetic, evidently on the suspicion that an abscess existed. In May, 1915, he was transferred to the United Kingdom and invalided out of the Service on account of continual pyrexia and recurrent attacks of phlebitis.

Apparently thrombosis of the veins began in the left leg, causing great pain and spreading via the pelvis into the right. Some three months subsequently compensatory enlargement of the abdominal veins was noted, which gradually formed a large abdominal plexus. He was unfit for service through the whole of the war, suffering from intermittent attacks of pyrexia and phlebitis and secondary ulceration. In February, 1920—i.e., five years and two months after original attack—pleuritic pains in the right side commenced with cough, profuse expectoration, often blood-tinged. The fingers became numb and cold and the terminal phlanges gradually became clubbed.

At that time he was thought to be suffering from pulmonary tuberculosis, and an unfavourable prognosis was given. Admitted to hospital on Nov. 8th, 1920, he was found to be in a distressed condition, harassed by constant cough, expectoration, and pain in right side. The temperature was hectic in type, emaciation was extreme, and the sputum was profuse, frothy and purulent, tinged from time to time with dark blood. In amount it varied from one to three pints in the 24 hours. This expectoration was usually brought up after an explosive coughing fit, and excited by change in posture; it was noted that bending to the left side was apt to initiate such a spasm. The clubbing of the fingers and toes was evident, and the superficial abdominal veins were varicose.

No evident enlargement of the liver was revealed by a physical examination, but the signs elicited on the right side suggested a considerable involvement of the lung tissue. Impairment of percussion, with diminished air entry and vocal resonance, extended downwards from the third rib. Posteriorly dullness commenced from the seventh space in the scapular line. The sputum contained numerous pus and large epithelioid cells; there was a definite leucocytosis of 14,000, while the fæces contained the cysts of *E. histolytica* in large numbers.

The liver was aspirated under an anæsthetic without result; immediate improvement took place from emetine and ipecacuanha therapy; the cough diminished; the expectoration became less in amount and the lung signs cleared up entirely. The clubbed fingers and toes gradually became normal. He received a total amount of 10 gr. emetine, 160 gr. pulv. ipecac., and 30 gr. emetine bismuthous iodide. After two months in hospital he was discharged as convalescent, having made a satisfactory recovery, with no pulmonary symptoms, and having increased 18 lb. in weight. The sequence of events in this remarkable case would appear to be as follows:—

Primary amœbic dysentery; amœbic hepatitis and formation of hepatic abscess, septic absorption from the abscess cavity and consequent thrombosis of the saphena veins, compensatory venous circulation; rupture of hepatic abscess through diaphragm into right pleura, formation of secondary amœbic abscess of lung, with clubbing of fingers and toes, and respiratory changes.

This man has remained in good health ever since.

CASE 5.—An Englishman, long resident in India, returned to this country on leave in May, 1921. He had been suffering from antral trouble for some time previously, but the present illness began suddenly on August 9th of that year, with what was thought to be an attack of pneumonia. His temperature was intermittent in type, reaching 103° F., profuse perspirations, and the sudden expectoration of purulent fluid containing a considerable amount of dark blood. He became rapidly emaciated and lost over 2 st. in weight, the lowest recorded being 8 st. 13 lb. The amount of expectoration varied very considerably from day to day, apparently being influenced by posture. On admission to hospital on Oct. 10th he was found to have very considerable involvement of the right lung, with a pleuritic rub and diminished air entry; there was also impairment of the percussion note at the left base with sonorous rhonchi and scattered crepitations. The sputum was copious and purulent, averaging about a pint daily and containing large numbers of pus and epithelioid cells, no entamœbæ, but large numbers of yeast cells and branching mycelium. The organisms, cultured by Dr. J. T. Duncan, were found to have the characteristics of the genus monilia, and to be serologically similar, as tested by agglutination and complement deviation, to stock cultures of the thrush fungus. They are of the type commonly isolated by this investigator from fæces. The liver was not apparently enlarged, nor could any evidence of its implication be obtained from an X ray examination. The blood showed a definite leucocytosis of 12,000. The fæces contained no *E. histolytica* cysts. The improvement on emetine injections and pulv. ipecac. was rapid and remarkable, the amount of sputum diminished, and before he left for India in March, 1922, he had gained 47 lb. in weight. He has remained in good health ever since.

The hepatic abscess in this case must have been in the process of formation for some considerable time without producing any obvious symptoms; in fact, its rupture into the lung substance appears to have been the first evidence of its existence. The presence of yeast cells and mycelium in the sputum in large numbers, apparently derived from the lung cavity, is of interest.

One cannot regard the thrush fungus as the cause of the disease, but as being a secondary infection. In a similar manner Monilia often occurs in the sputum of tuberculous subjects, and other debilitated subjects. That this is not the view held by all may be judged by the amount of literature devoted to the condition described by Castellani as tropical bronchomycosis or bronchomoniliasis,[10] about the pathology of which little appears to be known. Castellani says that "the diagnosis of moniliasis is based on the finding of the fungus in the sputum." Adopting this criterion, the case quoted above should have been regarded as a primary infection of the lung with Monilia, and not as a case of pulmonary amœbiasis, as it turned out to be

Conclusions.

1. Pulmonary amœbiasis may develop independently of hepatic abscess.
2. The pulmonary condition may simulate those of a bronchopneumonia or miliary tuberculosis.
3. The diagnosis is based upon the previous evidence of amœbiasis, the leucocytosis, and the remarkable and lasting response to emetine and ipecacuanha.
4. Rupture of a hepatic abscess into the lung may take place without previous warning or the coexistence of hepatic symptoms.
5. The resulting pulmonary infection may closely resemble idiopathic disease of the lung, such as tuberculosis or bronchiectasis, both in local signs and general effects.
6. The therapeutic action of emetine and ipecacuanha is as striking in this as in the first condition described and, as generally recognised, is more rapid and lasting than in amœbic infections of the bowel.
7. Secondary infection of the respiratory tract with yeast fungi (Monilia) may occur (so-called bronchomoniliasis). This appears to be of little diagnostic and possibly of no ætiological importance.

I am indebted to Dr. J. T. Duncan for his help in the investigation of these cases, and to my senior colleague, Dr. G. C. Low, for his kindness in permitting me to utilise his notes of the third case quoted. Capt. R. L. Sheppard has given me considerable assistance with the scattered literature of this subject.

GASTROMYOTOMY:

AN OPERATION FOR THE CURE OF CHRONIC ULCER OF THE STOMACH.

By T. C. CLARE, M.D. Lond., F.R.C.S. Eng.,
SURGEON, LEICESTER ROYAL INFIRMARY.

Gastro-enterostomy for the cure of gastric ulcer is out of favour, whether alone or combined with excision or cauterisation of the ulcer. Sir Berkeley Moynihan,[1] in a recent Hunterian Lecture, has stated that its "trivial advantages" are outweighed by its disadvantages, the chief of which is that the relief that follows the operation is frequently only temporary. Most surgeons will agree that the operation is by no means ideal for ulcers in that situation, and will admit the force of the arguments that he brings forward in his advocacy of the very radical operation of partial gastrectomy. The surgical mind, however, cannot contemplate with perfect satisfaction the necessity of having to choose between medical treatment on the one hand and gastrectomy on the other. If no less hazardous and mutilating operation can be devised for the cure of these ulcers, the inevitable tendency will be to postpone surgical intervention and to try medical treatment for longer than would otherwise be the case. But surgeons will continue to search for a simpler and safer operation, bearing in mind, perhaps, that if they can, by such an operation, bring about "a complete subsidence of all symptoms, a permanent freedom from any recurrence of the like disease, and immunity from any disorder associated with the operation"[1] in a *majority* of the cases, the operation of gastrectomy still remains for those few, if any, in whom the symptoms are not relieved or recur. For the operation about to be described it is claimed (1) that it is based on sound physiological principles; (2) that it may fairly be described as a safe and a simple operation; (3) that the results in the few cases in which it has been performed have been good.

The principles on which the operation is based may first be considered.

Cause of the Chronicity of Gastric Ulcers.

Leaving aside the question of the actual origin of gastric ulcer, there is general agreement on three points in connexion with the subject: first, that chronic ulcers are found, in the great majority of cases, in two situations only—on or near the small curvature and on or near the pylorus—while acute ulcers are not so limited in their distribution; secondly, that healing of gastric (and duodenal) ulcers is a common event (Prof. M. J. Stewart[2] has brought forward conclusive evidence on this point from post-mortem examinations); thirdly, that there is no known reason, anatomical or physiological, why ulcers should *originate* in one part of the stomach more than in another. We may draw the inference, therefore, that there is some factor in connexion with the small curvature and the pylorus that delays or prevents the healing of ulcers near these parts. I believe that this factor is to be found in the arrangement of the circular muscle fibres in these parts. In the case of the pylorus there is an easily demonstrable sphincter; in the lesser curvature, the circular fibres that are comparatively thinly spread over the fundus and the great curvature are crowded into a smaller space and set so close together as almost to constitute a sphincter. It is a fundamental principle of pathology that rest is conducive to the healing of a wound, while movement and irritation hinder healing. While no part of the stomach is at rest for any length of time, unless feeding by the mouth is discontinued, and probably not even then, an ulcer originating in a part where the muscle fibres are sparsely distributed, such as the great curvature, has a much better chance of healing than one which happens to start in the sphincter of the pylorus or the small curvature. A fissure of the anus involving the sphincter ani heals slowly, perhaps not at all; when the muscle is divided the fissure heals rapidly, in spite of the septic nature of the material that passes over it. It occurred to the writer that treatment on these lines might allow natural healing to take place in chronic ulcers of the stomach, and that it might prove more profitable to focus attention on the muscular fibres rather than on the gastric juice or on dental sepsis. The operation consists of a division of the circular muscle fibres that pass to the neighbourhood of the ulcer. "Gastromyotomy" seemed a convenient and self-explanatory name for the operation.

Technique of the Operation.

I have performed gastromyotomy only in cases where laparotomy has revealed a chronic indurated ulcer of moderate size in the neighbourhood of the small curvature, uncomplicated by hour-glass contraction and not adherent to the pancreas, though I am not sure that the latter complication would contraindicate the operation. If the ulcer is on the anterior wall of the stomach, a curved incision, about four inches long, with the convexity downwards, is made below the ulcer and sufficiently far from it to be free of indurated tissue; this incision divides the peritoneal coat only. The peritoneum is separated from the muscular coat for about a quarter of an inch on each side of the incision, and the muscle fibres are defined. The incision is then carried down to the muscularis mucosæ, thus dividing all the circular muscle fibres passing to the ulcer-bearing area. This part of the operation is a little difficult, as the fibres are sometimes indistinct and it is easy to penetrate the mucous membrane; should this occur it is sutured before proceeding. The divided muscle fibres are now separated on either side of the incision by means of gauze wiping, and the peritoneal coat sutured by Lembert sutures in such a way that the cut edges of the peritoneum are inverted into the gap that has been made in the muscular coat. I have once or twice cauterised and infolded the ulcer, but am not convinced that there is any particular advantage in so doing. After the usual inspection of the appendix, &c., the wound is then closed. Where the ulcer is on the posterior wall I have exposed the stomach through an opening in the mesocolon and made the incision in the posterior wall of the stomach; but as the muscle fibres appear to be thinner in that situation than in the anterior wall, I have made the anterior incision as well, thereby practically isolating the ulcer as far as the circular muscle fibres are concerned.

As regards after-treatment, patients have been treated much in the same way as those in whom gastro-enterostomy has been performed—salines and glucose for 24 hours, feeds of milk, &c., going on to fish and minced chicken in about a week, and ordinary food soon after. Alkalis have not been given.

Results.

In no case has there been any pain after the operation, nor any vomiting, apart from slight post-operative vomiting. In one patient, in whom even feeds of milk caused pain up to the day of operation, the pain entirely disappeared and has not recurred, though she has been taking ordinary food with good appetite for some months. This has been perhaps the most striking case, for in the other cases careful dieting and medical treatment combined with rest in bed had relieved the pain for a week or so before operation. In one patient, who was markedly anæmic from gastric hæmorrhage, the melæna, which disappeared immediately after the operation, recurred and did not entirely clear up until the twelfth day. In this case the base of the ulcer was very thin and was cauterised and infolded; some leaking apparently occurred and the upper part of the wound suppurated for a few days. There has been no pain or vomiting since the operation and six months after discharge the melæna has not recurred.

One patient complained of occasional attacks of vomiting a month after operation, but in her case permission to take ordinary food was too liberally interpreted, and vomiting has ceased since reasonable care has been taken in the selection of diet. In one case I had occasion to reopen the abdomen two months after performing this operation. The patient was a man of 37, with a three months' history of pain one and a half hours after food, and two recent attacks of hæmatemesis. There was a large ulcer in the anterior wall of the stomach, close to the small curvature and at the junction of the cardiac and pyloric parts of the stomach. There was so much induration around the ulcer that I was suspicious of malignancy, but decided against it. Gastromyotomy (anterior wall only) was performed and for eight weeks there was no pain after food, and the man improved remarkably in general condition and put on weight. He then began to complain of pain, not related to food, but coming on at night; there was considerable delay, one-third of the meal remaining after eight hours, and I began to think that I had made a mistake in not treating the condition as malignant. I reopened the abdomen and found that the extent and degree of the induration had greatly diminished and no longer suggested malignancy; the crater of the ulcer, however, could still be felt, although it was smaller and smoother than at the first operation; there was no sign of any scar where the muscular coat was divided at the first operation. Gastro-enterostomy was performed because of the delay. In an almost exactly similar case, where division of the muscular coat was carried out in both anterior and posterior walls, the result after six months is most satisfactory, and I am inclined to think that the division of the fibres on both sides of the ulcer will prove to give better results than on one side only.

Rôle of Gastro-enterostomy in Gastric Ulcer.

There is no doubt that the results of gastro-enterostomy for gastric ulcer are frequently very good, though symptoms are apt to recur. Some attribute the beneficial effects of the operation to the neutralisation of the acid gastric juice by the alkaline contents of the duodenum which flow into the stomach through the stoma, while others, including Moynihan, consider that the mechanical factor, the simple drainage of the stomach, is the chief effect of the operation, the rapid emptying of the stomach affording rest to the ulcer and so facilitating healing. The performance of gastro-enterostomy, however, introduces a third factor to which I believe attention has not hitherto been directed, but which I venture to suggest has an important bearing upon the results of the operation. This factor is the abolition of the sphincter action of the circular muscle fibres divided by the incision from which the stoma is made. If these fibres are those that pass to the ulcer and its immediate neighbourhood, the ulcer is placed at rest, as far as the circular fibres are concerned, though it may still be dragged upon by the longitudinal fibres, which are set close together along the small curvature. Not only are the fibres divided; they are, by the anastomosis, prevented from ever uniting again. An incision that will divide all the fibres passing to an ulcer on the small curvature will clearly have to be considerably longer if it is placed near the great curvature than if it is nearer the ulcer. For an ulcer of moderate size it will have to be of considerable length, and this perhaps may be the explanation of the fact that a large stoma gives better results than a small one, even though the latter is larger than the normal pyloric opening. That drainage of the stomach alone is not sufficient to cause healing was shown by Fibich,[8] who drained by a narrow tube the stomach of dogs in whom chronic ulcers had been artificially produced; the ulcers did not heal, though they healed readily after gastro-enterostomy.

I suggest, therefore, that the operation of gastro-enterostomy, when performed for ulcers of the small curvature, or of the anterior or posterior wall near the small curvature, is, in effect, simply a "gastromyotomy," that the drainage of the stomach and the neutralisation of the gastric juice are not the important factors, and that what the operation really succeeds in doing is to put out of action some at least of the muscle fibres that pass to the ulcer. If there is any truth in this view a much simpler operation should suffice. It is only necessary to divide the muscle fibres and to prevent them from uniting too quickly and the same result will be produced. In the operation that I have described the curved incision, fairly close to the ulcer, divides all the fibres, circular and longitudinal, that pass to the ulcer, and is shorter than an incision at the great curvature would have to be to divide only the same circular fibres.

We have no certain knowledge concerning two points in connexion with the operation of gastromyotomy. First, the length of time required for healing to take place in an ulcer immobilised by section of muscle fibres; secondly, the length of time before the divided fibres unite and function is restored. As regards the first point, Eve reported a case where he has performed gastro-enterostomy for an ulcer in the pyloric part of the stomach associated with considerable inflammatory thickening; laparotomy had to be performed five weeks after the first operation, and it was found that the ulcer had completely disappeared, its site being indicated merely by an omental adhesion. Several somewhat similar cases have been reported. It may, therefore, be taken that, under the most favourable circumstances, complete healing may be a matter only of a few weeks. It may be mentioned that the most favourable conditions are not necessarily secured by keeping the stomach empty and feeding the patient through a tube in the jejunum, for the gastric muscles probably contract, either tonically or rhythmically, even when the stomach is empty; it is doubtful, for example, if an anal fissure could be made to heal by performing colostomy and leaving the sphincter ani intact.

Pyloric Ulcers.

Though it is true, as Sir Berkeley Moynihan points out, that ulcers involving the pylorus have their origin on one side or other of the sphincter and are either gastric or duodenal, nevertheless there is a certain appropriateness in the designation "pyloric" as applied to these ulcers. For, if it is true, as I believe, that it is the invasion of the muscular coat by these ulcers that is responsible for the delay in healing, then the significant thing about an ulcer in this situation is not whether it has originated on one side or the other of the pylorus, but the fact that it has actually invaded the muscular fibres of the pylorus, and is therefore disturbed and irritated by every wave of contraction that passed through these fibres. With the object of setting the ulcer at rest, I have on several occasions in the last few years, in cases of pyloric ulcer, divided the pylorus down to the mucous membrane in addition to performing gastro-enterostomy; the peritoneal coat was united, leaving, as far as possible, the muscle fibres ununited. The cases, however, have been too few to enable one to say whether the step was of any particular value.

During the last six months I have treated four cases of duodenal ulcer involving the pylorus by simple division of the circular fibres without gastro-enterostomy. Though the results have been good and all symptoms have disappeared, I am not entirely convinced by them, and am certainly not prepared, without further experience, to claim that this operation is suitable for all cases of duodenal ulcer. My reasons for hesitating to draw conclusions from these four cases are first, that though the symptoms were definite enough, the ulcers were in each case small, and only indicated by slight scarring on the peritoneal surface without thickening and by slight omental adhesions; secondly, that the muscular coat of the duodenum is so thin and ill-defined that it is difficult to identify it and to separate the peritoneal coat from it, and consequently one is uncertain whether in suturing the latter some of the muscle fibres have not been included. If this should happen, union would presumably take place too soon to allow of a sufficiently long period of rest for the ulcer to heal. Where there is actual stenosis of the pylorus obviously gastro-enterostomy is necessary.

Musculature of the Stomach.

Radiologists have taught us that the stomach may be divided into two parts—a "cardiac sac" where peristaltic action is sluggish, and a pyloric part where it is very active. The arrangement of the muscular fibres shows that there is an anatomical basis for this division. The circular fibres are only truly circular in the pyloric part of the stomach and to the left of the cardiac portion; in the greater part of the cardiac half they are U-shaped, and so incapable of acting as true sphincters. From the incisura angularis to the pylorus the circular coat is well marked, and strong peristaltic waves pass along it from the time that food enters that part of the stomach from the cardiac sac until the stomach is empty. Furthermore, there is at the incisura a sphincter (physiological only, according to Starling), called by Sir H. M. W. Gray the "sphincter aditus vestibuli,"[4] whose function appears to be to confine the food in the cardiac sac until it is ready to pass into the pyloric pouch. The longitudinal fibres constitute the external coat and are set closer together along the small curvature than elsewhere, while the oblique fibres are distributed chiefly over the fundus and the cardiac sac. Chronic ulcers are found most commonly in the pyloric half of the stomach, and generally nearer the small curvature than the greater, and I suggest that this distribution is due, not to a greater liability to acute ulceration in these parts, but to the fact that the greater activity of the muscles tends to prevent healing of ulcers sufficiently deep to have involved the muscular coat; while the comparative freedom of the cardiac sac (except near the incisura) from chronic ulcer is due to the less vigorous and less prolonged peristaltic action in that part.

Both W. J. Mayo[5] and Sir H. M. W. Gray[4] have pointed out the importance of performing gastroenterostomy in the pyloric half of the stomach, though for different reasons; Mayo, for the reason that much of the food passes over the stoma if it is placed in the cardiac half, while Gray believes that it is important to conserve the functions of the cardiac sac and drain the pyloric half in order to obviate the ill-effects of pyloric spasm. I suggest that the benefits arising from making the stoma in the pyloric half are due to the fact that the circular fibres passing to the ulcer are divided and kept apart by the anastomosis, the sphincter action of the fibres being thus abolished, and to the fact that drainage of the stomach is not the essential factor, and is, indeed, probably unnecessary. The operation that I have described is an attempt to apply to ulcers of the stomach the great principle of surgery that rest is the most important factor in the healing of wounds. I have performed the operation in nine cases in the last eight months; the number is too small, and the time since operation too short, for the results alone to carry conviction. I mention them to support a view of the pathology of chronic ulcer of the stomach that I believe to be worthy of consideration. Whatever may be the ultimate results of the operation in these cases, it can certainly be said that the immediate results have been satisfactory. In all the cases there had been typical epigastric pain for months or years, all had been treated medically for some considerable time without lasting benefit, and in the gastric cases in each case the ulcer was large enough to admit the tip of the little finger. In one case only has there been any pain since operation; all the patients have been taking ordinary food and have put on weight. In one case of ulcer of the anterior wall, though pain and vomiting had ceased, some loss of weight was observed four months after operation, and it was discovered that she had diabetes, which was not present at the time of operation. Gastromyotomy is a simple and safe operation, and, I believe, only temporarily affects the functional activity of the stomach, but it need hardly be said it is not applicable to cases where there is stenosis or hour-glass contraction, or anything but a simple ulcer. For an operation so free from risk, from which convalescence is so rapid (as indeed is the case in most gastric operations), and which offers a good prospect of complete recovery, with the preservation of the normal physiology and anatomy of the stomach, I think we may fairly hold the view that even if there should turn out to be a small proportion of recurrences, the operation is not condemned thereby. More radical measures are still available if the ulcer should recur.

Gastromyotomy is the link between medical and surgical treatment; the aim of medical treatment is to encourage healing by diminishing functional activity and so resting the stomach; the operation secures rest by putting out of action for a time the actual muscle fibres whose contractions irritate the ulcer. All that I could claim for this operation, and more, might be expressed by saying that if at the time when the "Lectures on Rest and Pain" were written gastric ulcer had been a surgical condition, such a view of its pathology as I have tried to bring forward, and perhaps such an operation as the above, would have appealed to John Hilton.

ALKALI DEFICIT* IN NEPHRITIS.

By JOHN R. MARRACK, *D.S.O.*, M.D. Camb.

(From the Hale Clinical Laboratory, London Hospital.)

On ordinary diet, as a result of oxidation of neutral sulphur and phosphorus in the food to form sulphuric and phosphoric acids, and of the formation of organic acids, an excess of non-volatile acids arises daily, equivalent to about 500 c.cm. of N/10 solution, which should be excreted by the kidneys. When the kidneys are inadequate for this task retention of acid occurs, just as retention of urea occurs when the kidneys are unable to excrete urea as fast as it is formed. Because as a general rule, on ordinary diet, the kidneys are presented with an excess of acid to excrete, alkali deficit is more common than alkali excess in untreated cases of nephritis.

Methods for Detection of Alkali Deficit.

Many methods have been used for detecting the presence of alkali deficit; of these the most satisfactory is the estimation of the bicarbonate content of the plasma, preferably together with the hydrogen-ion concentration of the plasma. This gives direct information as to the actual balance of acids and bases in the blood, and indirectly in the other body fluids also. When the respiratory centre, heart, and lungs are carrying out correctly the regulation of blood reaction by control of CO_2 excretion, the CO_2 tension of alveolar air gives the same information, but in nephritis this regulating mechanism may be profoundly disturbed by interference with the blood-supply of the respiratory centre, heart failure, and œdema of the lungs, and the alveolar air becomes an unsatisfactory index of the condition of the body fluids.

Any method that depends on titrating the serum or plasma to an end-point distant from that of plasma, as, for example, to the yellow-red changing point of methyl orange, the agglutinating point of red blood corpuscles, or the iso-electric point of serum globulin, are fallacious, as they involve titration of the proteins of the plasma or serum. The factor thus introduced is variable, as the protein content of the plasma varies, especially in nephritis. When the kidneys are damaged it is obviously impossible to use them as indicators of the state of the blood and other body fluids, as they may excrete an alkaline urine when the blood contains an excess of acid, or vice versa. For this reason the method of alkali tolerance—the determination of the amount of sodium bicarbonate, given by the mouth, required to make the urine alkaline—though very unsatisfactory when the kidneys are healthy, is entirely fallacious in nephritis; in this condition it is no more justifiable than would be an attempt to titrate an acid with a faulty indicator.

---

* Owing to the confusion that has arisen as to its meaning, the familiar term "acidosis" has not been used for the condition in which an absolute or relative excess of non-volatile acid in proportion to alkali is present in the blood; Van Slyke's term "alkali deficit" is used instead. The term "acidæmia," recommended by the Medical Research Committee, is not suitable, as it is defined as an increase in the hydrogen-ion concentration of the blood, which may or may not accompany alkali deficit.

The results of plasma bicarbonate determinations are usually expressed as the number of c.cm. of CO_2 that the bicarbonate in 100 c.cm. of plasma would give off on treatment with excess of acid, although this method of expression is undesirable, as in order to determine the effect of the retention of a given amount of acid on the plasma bicarbonate it is convenient to have both expressed as gramme equivalents per litre. The normal figures for plasma bicarbonate expressed in the customary manner range between 55 and 70. Cases of alkali deficit may conveniently be classified into mild with plasma bicarbonate between 45 and 54, moderate between 35 and 44, and severe under 35. In the more severe cases the increased lung ventilation fails to keep down the dissolved CO_2 in the plasma in proportion to the reduced plasma bicarbonate, with the result that the hydrogen-ion concentration of the plasma rises; this, however, does not occur in the less severe cases.

In the more severe cases of alkali deficit, in interstitial nephritis at any rate, some one-sixth to one-half of the reduction of plasma bicarbonate is accounted for by retained phosphoric acid; other acids, sulphuric among them, account for the remainder. The condition does not develop rapidly. Thus a patient who had had an extreme degree of alkali deficit and renal incompetence was given sodium bicarbonate, and her plasma bicarbonate brought back to normal; after the alkali administration had been stopped her plasma bicarbonate fell from 51 to 41 in a week; the patient was taking little carbohydrate, so that the acid production from the oxidation of protein must have been large.

Incidence of Alkali Deficit in a Series of Cases.

The incidence of mild, moderate, and severe alkali deficit in 216 examinations of patients who had not been treated with alkalis, arranged according to the height of the blood-urea, are shown in the table.

Showing Incidence of Alkali Deficit in a Series of Cases Arranged According to the Height of their Blood-urea.

—		Blood-urea in mg. per 100 c.cm.		
		Under 50.	50–100.	Over 100.
Total number of estimations		102	60	54
Alkali deficit	Mild	3	9	12
	Moderate ..	1	3	9
	Severe	0	1	13
	Of all degrees ..	4	13	34

In the one instance of a moderate alkali deficit with a normal blood-urea the patient had been having fits with clonic contractions for some hours, and the alkali deficit was probably, in part at least, due to accumulation of lactic acid. The three patients with mild alkali deficit in this group were all recovering from acute nephritis.

It appears from this table that alkali deficit is rare in patients with fairly efficient kidneys, and frequently, but not invariably, present in patients with severe kidney inefficiency. The higher incidence found by other methods is due to faults mentioned above. The severity of the condition is further shown by the death-rate; of seven patients with moderate alkali deficit four died within two weeks; of 14 with severe alkali deficit five died within a few days and five more within a month.

Associated Conditions.

As may be expected, alkali deficit and uræmia are frequently associated, but the alkali deficit itself seems to play no part in causing any of the symptoms of uræmia. Uræmia often occurs in patients with normal plasma bicarbonate, and is absent in others with severe alkali deficit; while patients in whom the plasma bicarbonate has been brought back to normal from a very low figure and maintained about normal may, after the lapse of some days or weeks, develop uræmia. Dyspnœa is very rare with alkali deficit in nephritis; hyperpnœa may be present, but is usually not striking. Actual dyspnœa and Cheyne-Stokes breathing occur rather in patients with arterial degeneration or some degree of heart failure, and are due to disturbance of the blood-supply of the respiratory centre. Headache and vomiting are no more common in patients with alkali deficit than in those without; in fact, the striking feature is the small effect that even an alkali deficit with increased hydrogen-ion concentration has—which fact supports the now generally accepted theory that the symptoms observed in diabetic ketosis are due not to the alkali deficit per se, but to the nature of the acids retained, and enforces the undesirability of confusing the terms "acidosis" and "ketosis."

Treatment.

Unlike other disturbances in severe nephritis alkali deficit is amenable to treatment, and treatment of the more severe degrees is certainly advisable, as the body will not stand more than a certain increase in the hydrogen-ion concentration of the body fluids, and as the bicarbonate falls the change in hydrogen-ion concentration produced by a given increase of retained acid steadily rises. On the other hand, the urgency of the need of alkali is not so great as to demand such emergency methods as intravenous injection, as there is not the rapid production of acid such as may take place in ketosis, and enough alkali can be given by the mouth to neutralise any fresh acid that may be formed and leave an excess for increasing the plasma bicarbonate. Rectal administration should not be employed, as it is impossible to form an accurate estimate of the amount absorbed.

The oral administration of sodium bicarbonate by the mouth has its dangers. Nephritics are unable to get rid of an excess of alkali as well as an excess of acid, and if excess is given a condition of alkali excess is produced, a condition more dangerous than alkali deficit, although it tends to cure itself if alkali administration is stopped. For this reason the amount of bicarbonate given should not be more than required to bring the plasma bicarbonate back to normal. Also the administration of large doses of sodium bicarbonate alone is liable to upset the balance between sodium, potassium, and calcium in the body fluids; for this reason potassium and calcium should be given at the same time. Calcium administration is all the more necessary as plasma calcium is often low in nephritis with alkali deficit. Again, administration of large doses of sodium bicarbonate often leads to increased retention of water, and increases œdema and the danger of œdema of the lungs; this provides further reason for keeping the amount given as low as possible. It is therefore desirable to give about as much sodium bicarbonate as will bring the patient's plasma bicarbonate up to 40; this removes the danger of the development of a fatal hydrogen-ion concentration. The amount required to do this can be calculated from the formula $g = W\ (40 - x)\ /2$, where x is the patient's plasma bicarbonate before administration, W his weight in kg., and g the number of grains of sodium bicarbonate required. With this should be given $\frac{g}{20}$ gr. potassium bicarbonate, and calcium lactate. Having brought the plasma bicarbonate up to this level, the production of acid should be kept as low as possible by feeding the patient on a mainly carbohydrate diet to reduce the production of acids from food protein or from the patient's own tissues to a minimum, and moderate doses of sodium bicarbonate—e.g., 20 gr. three times a day—should be given. Such treatment will not prevent the patient from dying from other causes; it may not prolong life, but it removes the risk of death from uncompensated alkali deficit.

Illustrative Cases.

The following cases illustrate points considered in this paper:—

CASE 1.—Severe alkali deficit; death probably accelerated by administration of large doses of sodium bicarbonate.

Female, aged 17, subacute parenchymatous nephritis. Œdema of arms and legs began in June, 1922. On Jan. 26th, 1923, general œdema; systolic blood pressure, 170 mm.; no cardiovascular hypertrophy. Urine scanty, albumin ¼ volume, granular casts. Red blood corpuscles, 1·4 million per c.mm.; Hb, 35 per cent. On the 27th plasma bicarbonate, 21; pH, 7·3; blood-urea, 320 mgm. per 100 c.cm. Mind clear; no hyperpnœa. On the 29th 1 dr. sodium bicarbonate, with proportionate amounts of potassium bicarbonate and calcium lactate, given every three hours. Gained 29 oz. in weight during next 24 hours, although she had, since admission, been losing weight. Died on evening of the 30th.

Post-mortem Examination.—Subacute lipoid parenchymatous nephritis; slight cardiovascular hypertrophy; very great œdema, and considerable congestion of lungs; general œdema.

CASE 2.—Severe alkali deficit; onset of uræmia after the acidosis had been somewhat reduced. Female, aged 17, out of sorts for seven months. July 18th, 1922, very slight œdema; blood pressure 162 mm. systolic, 80 mm. diastolic; bleeding from gums. On the 20th mind quite clear; slight dyspnœa on speaking much. Red blood corpuscles, 2·5 million per c.mm.; Hb, 35 per cent. Urine: albumin ⅓ volume; deposit pus. Plasma bicarbonate, 16; pH, 7·2; blood-urea, 320 mg. per 100 c.cm. On the 21st 500 c.cm. 2 per cent. sodium bicarbonate given intravenously; and ½ dr. by mouth every four hours. On the 22nd plasma bicarbonate, 28; pH, 7·4; blood-urea, 320 mgm. per 100 c.cm. General convulsions and coma, with intervals of consciousness, set in at 2 P.M.; later coma became continuous and death ensued on the morning of the 23rd.

CASE 3.—Very severe alkali deficit; uræmia and death after plasma bicarbonate had been maintained at a level little below normal for some weeks. Female, aged 25. Chronic interstitial nephritis. Breathless and giddy during last three or four years. Swelling under eyes since August, 1922, vomiting since September. Urine: Albumin, 1/10 volume, small amount of pus, daily output about 1200 c.cm. Very severe anæmia. Nov. 16th, 1922, drowsy, no hyperpnœa nor dyspnœa. Plasma bicarbonate, 13; pH, 7·2; blood-urea, 343 mg. per 100 c.cm. At midnight she was given 350 c.cm. 2 per cent. sodium bicarbonate intravenously, followed by a drachm of sodium bicarbonate by the mouth every three hours; on the 17th and 18th 1 dr. given every two hours with 3 gr. potassium bicarbonate, and 10 gr. calcium lactate. These salts were given every four hours on the 19th and discontinued on the 20th. On second two days of administration the output of urine was about 2 litres less than the intake of fluid. On the 20th plasma bicarbonate, 74; pH, 7·55; blood-urea, 400 mg. per 100 c.cm. On the 22nd muscular twitching, headache, and vomiting. On the 23rd plasma bicarbonate, 51; pH, 7·45; blood-urea, 505 mg. per 100 c.cm. On the 30th plasma bicarbonate, 41; pH, 7·35; blood-urea, 600 mg. per 100 c.cm. On Dec. 4th bicarbonate mixture given again with calcium lactate every four hours until death. On the 7th plasma bicarbonate, 48; pH, 7·35; blood-urea, 480 mg. per 100 c.cm. Patient died on the 8th after one fit.

Post-mortem Examination.—Very great destruction of kidney substance by chronic interstitial and little acute parenchymatous nephritis. Very great œdema of lungs, general œdema, ascites (1 pint), bilateral pleural effusion (½ pint each side).

CASE 4.—Severe alkali deficit with little disturbance. Female, aged 31, congenital cystic kidneys. History of polyuria and frequency since infancy. No cardiovascular hypertrophy; blood pressure, systolic, 135 to 145 mm.; diastolic, 85 to 90 mm. Able to do a moderate amount of work. Urine: Low specific gravity, containing a small amount of albumin and pus. From July, 1921, to March, 1922, phenolsulphonephthalein excretion in two hours from traces to 13 per cent.; urea-concentration test, 0·8 to 1·35 per cent.; blood-urea, 90 to 114 mg. per 100 c.cm.; plasma bicarbonate, 52 to 55. On Oct. 26th, 1922, still feeling well and able to work; no noticeable hyperpnœa. Plasma bicarbonate, 33; pH, 7·2; blood-urea, 141 mg. per 100 c.cm.

CASE 5.—Uræmia without alkali deficit. Male, aged 51. History of six months' illness with failing sight, weakness, and shortness of breath; later vomiting. On July 30th, 1921, two fits in the night; on the 31st unconscious with muscular twitching. Systolic blood pressure, 140 mm.; no cardiovascular hypertrophy. Urine only 46 oz. in three days; specific gravity, 1009; trace of albumin, deposit of pus. On the 31st plasma bicarbonate, 69; blood-urea, 152 mg. per 100 c.cm. Patient died on August 2nd.

I owe my thanks to the physicians of the London Hospital for the facilities they have afforded me in the study of their cases.

Reviews and Notices of Books.

HYGIENE AND PUBLIC HEALTH.

Seventh edit. By LOUIS C. PARKES, M.D., and Prof. H. R. KENWOOD. Lewis's Practical Series. London: H. K. Lewis and Co., Ltd. 1923. Pp. 783. 20*s.*

THE new edition of this well-known volume will deservedly hold its own in popularity as a text-book for public health students. The authors have endeavoured to embody recent advances in public health and sanitary science without increasing the size of the book—no easy task, when we consider how the scope of public health work has been widened by the inclusion of schemes for dealing with tuberculosis, maternity and child welfare, medical inspection of schools, venereal diseases, &c., and also how views and methods have changed with regard to water purification, sewage disposal, nutrition, and ventilation. The greater interest awakened in physical development, light treatment, smoke prevention, industrial hygiene, and tropical diseases also demands some satisfaction from a text-book. The authors have wisely decided to omit the chapter on sanitary law, references being, of course, made throughout the text to the laws and regulations on the subjects treated. Examining bodies are rather too fond of setting questions of a legal nature to candidates for sanitary certificates and diplomas. It is too often forgotten that town clerks and legal luminaries do not trust to their memory of sections of Acts of Parliament when taking proceedings.

When the time comes for the next edition, we think the authors will be well advised to lighten the ship still further by omitting or shortening the references to more or less obsolete appliances and matters of purely historic interest. For example, in these days, when the cult of the open window is being practised or preached for the ordinary dwelling-house, and in view of the recognised uncertainty as to whether in the absence of mechanical power the air in a so-called ventilation duct will move according to plan, there is little necessity to devote space to such things as Tobin's tubes, Ellison's conical bricks, and Montgolfier's formula. On the other hand, more space might usefully be devoted to smoke prevention. Similarly under the heading Biological Purification of Sewage, while there is an interesting history of methods adopted since 1891, the authors have not found space for any account of the Sheffield system which formed the subject of a leading article in our issue of May 27th, 1922. The "activated sludge" system is shortly described by the authors, but Mr. John Haworth, of Sheffield, found that by a simple process of churning with paddles he could get satisfactory aeration without using compressed air machinery. This process has passed the experimental stage and will be gradually applied to a dry weather flow of 15 million gallons in Sheffield. It is also in use in Paris, Glasgow, East Ham, and Rotherham, and schemes are in course of construction in other towns. There are, of course, many things in this many-sided book which invite criticism, according to the views of the critic. We do not think Sir Henry Gauvain would endorse the views of the authors (p. 289) on the clothing of children, and we are not sure that, apart from footgear, women do not dress as hygienically as men nowadays. A text-book on public health cannot deal exhaustively with all the diseases which come under review, but surely the risk of the oncome of rickets (pp. 313 and 314) should be placed earlier, to be in accord with modern views.

A chapter of 200 pages is devoted to communicable diseases and a good account is given of each with the methods suitable for prevention. We missed, however, that modern plague of Egypt—bilharziasis. We note one or two errors in the indexing—e.g., vitamin 399 for 309, bilharzia 307 for 337, on which pages its life-history appears with that of the other human parasitic worms. Sir William Hamer's theory of the causation of enteric fever in London by fish is treated somewhat vaguely (p. 481). Chapters X., XI., and XII. deal effectively with maternity and child welfare, school hygiene, and industrial hygiene respectively.

We can heartily recommend the new edition of this book as an admirable introduction to the study and practice of public health.

COLLOIDS.

Théorie colloïdale de la biologie et de la pathologie. By AUGUST LUMIERE, Correspondant national de l'Académie de Médecine, Paris. Éditeur : Etienne Chiron. 1922. Pp. 202. Fr.16.

THERE are many volumes on the subject of colloids in circulation at the present time. The majority are much alike, taking as they do the perplexed reader through various colloidal properties such as Brownian movement, adsorption, electrical potential, and the like. In addition to all this, he is harassed with pages of complex mathematical calculations, with the result that usually his state of knowledge when he finishes the book is the same as when he started. Fortunately there have been some exceptions to this series of books, among which the volume at present under consideration has a certain amount of claim to be placed. It is not difficult to follow and is attractive in many ways, but its scientific value is unfortunately doubtful. The book is divided into two sections, the first dealing with a summary of colloidal properties in general and the application of colloidal principles to physiology, and the second with the part played by colloids in pathology. The first 20 pages are devoted to a description of colloids from a purely scientific standpoint. This section is very sketchy, only the barest outlines being given. Using this as a foundation, the author employs the remainder of the book to build a superstructure of speculation. A colloidal interpretation of the origin of life, evolution, and death is given. In the second part colloids are shown to play an important part in anaphylaxis, immunity, and cancer.

Though the book is devoted almost entirely to speculation, the arguments are presented with remarkable clearness and make good reading.

PRACTICAL BACTERIOLOGY.

Blood Work and Animal Parasitology. Seventh edition. By E. R. STITT, A.B., Ph.G., Sc.D., LL.D., Rear-Admiral, Medical Corps, and Surgeon-General, U.S. Navy. London: H. K. Lewis and Co., Ltd. 1923. Pp. 766. 21*s*.

IF called upon to go to some remote spot, being permitted the privilege of taking with them only one work of reference, the odds are good that of the great mass of practical laboratory manuals nine out of ten clinical pathologists would choose "Stitt." The present is the seventh edition of this invaluable work; it has been enlarged and brought thoroughly up to date, and several new sections and many new illustrations have been added. The book, although now comprising 766 pages, remains of compact form and of a size and shape which will enable it to slip readily into any ordinary coat pocket; this portability remains one of the most engaging features of this work; every available inch of paper is taken up, even to the insides of the covers, in pleasing contrast to the wide margins and liberal spacing which render the modern American manual a most unwieldy means for the dissemination of knowledge.

The descriptions of technique in all sections are concise but none the less quite full enough for guidance, and include in all departments not only old and tried methods but also most of the recent ones of any value. For example, in the section on media-making the useful method described not long ago by McIntosh and Smart for the preparation of routine media finds place. The failure to include a description of the Dreyer Sigma reaction in the section on flocculation tests for syphilis is an omission which should be rectified in the next edition. In the section on blood grouping the classification of Janssky as opposed to that of Moss has been adopted; this change is made in conformance with the decision of authoritative scientific bodies in the States; but though the author has taken trouble to make the matter clear, it holds the seeds of confusion for workers in this country. Note is taken of the work of Guthrie and Huck, published only last spring, on the possible existence of a further "agglutinogen" C; this work is so recent and untested that it was perhaps hardly wise to include it. In the section on the cells of the blood, that test-point for hæmatologists, the differentiation of large "hyaline" or "mononuclear" cells from large lymphocytes is competently dealt with; the work of McJunkin on phagocytosis by large mononuclears and their possible or probable endothelial origin might have been mentioned. Very valuable are the sections on helminthology and medical entomology, and this remains almost the only work of its sort in which poisonous reptiles and fish are noticed. The only real criticism that can be made of the book is the absence, no doubt deliberate, of references.

Practical Bacteriology for Chemical Students. By DAVID ELLIS, Ph.D., D.Sc., F.R.S.E., Head of the Department of Bacteriology and Botany in the Royal Technical College, Glasgow. London: Longmans, Green and Co. 1923. Pp. 136. 4*s*. 6*d*.

THIS little book contains a detailed account of the elements of bacteriological technique, arranged as a series of practical exercises. It is the endeavour of the writer to give the chemical student (and we gather his attention is directed more particularly towards the industrial chemist) a sufficient competence of bacteriological knowledge to enable him to investigate processes involving microbial growth when he finds it necessary to do so. Rather inevitably we tend to judge the book by the standard of medical bacteriology, and in doing so we cannot feel that it is quite adequate, or that the author's attempt will be successful. Over six pages are devoted to the staining of spores and cilia, processes which are seldom called for and of little practical use. Gram's stain is described with the omission of the counterstain. The student is told to make up sterile solutions of sugars, and to keep these in drop bottles for adding to his broth when the occasion arises! These we consider evil practices. There is also a frequent repetition of calculations of a most simple nature, such as the finding of the mean of eight whole numbers which occupies a half of page 82, and the titration of the acidity of fluid, on page 60; these are quite unnecessary and already known to any form of chemical student. Prof. Ellis's diction is at times a little unnerving. He constantly speaks of "diagnosing" bacteria, when he means identifying them, and he directs us, when we are about to stain our slide, to "clutch it with a pair of pincers." We note that Figs. 36 and 37 are absent, although reference to them appears in the letterpress. Probably the book will be useful in the special field for which it is designed; it is not suitable for medical students.

CHIRURGIE VASCULAIRE CONSERVATRICE.

Par P. MOURE, Chirurgien des Hôpitaux de Paris. Paris: Masson et Cie. 1923. Pp. 179. Fr.12.

THIS volume provides in a compact form a comprehensive account of the surgery of the blood-vessels. The first part of the book deals with the more general questions of operative technique, difficulties, complications, and results. The second part gives an account of the surgery of recent injuries to blood-vessels, of aneurysms, of embolism and thrombosis of arteries, and of vascular anastomoses and grafts. It is useful to possess in so accessible a form clear accounts of operations which are but seldom carried out by most surgeons. The text is aided by a great many reproductions of semi-diagrammatic drawings. These drawings are, indeed, so clear that many of the operations appear to be much simpler than they actually are in practice; but apart from this the book may be taken as a reliable guide to the subject with which it deals. The text contains a large number of references to other authorities.

POST MORTEM; ESSAYS HISTORICAL AND MEDICAL.

By C. MACLAURIN, M.B., C.M., F.R.C.S.E., LL.D., Lecturer in Clinical Surgery, University of Sydney. London: Jonathan Cape. 1923. Pp. 255. 7*s.* 6*d.*

IT was with great relief that we opened this book to find that it was not a farrago of eschatology such as not so long ago used to appear in a weekly journal, for from the simple title we had feared that such might be the case. Instead, we found a series of more or less historical essays dealing mainly with the question as to how their conditions of health affected for good or ill various people notable in the history of the world. Somehow, to know that the Empress Theodora suffered from cancer or to consider that Jeanne D'Arc was an instance of infantilism and sex repression makes them more real to some people than if they are looked at solely from the point of history. Dr. MacLaurin writes in a breezy, but attention-compelling fashion. Here and there he falls into strange errors, as, for instance, on p. 69, where he makes Nestorius the author of the Monophysite heresy, when it was actually Eutyches, who fell into the heresy owing to his violent opposition to Nestorius. In his essay on Theodora he recalls the well-known and oft-repeated fact that violent sexuality is in some way related to powerful religious instincts, and in another passage that her career as Empress is "the most extraordinary instance on record of living a thing down." There was a comparable instance in our own times in the case of Laura Bell, whose marriage in 1852 to Mr. Thistlethwayte, after a notorious career, excited so much interest in society in the fifties and after. She took to holding revivalist services and enjoyed the friendship of many eminent people, including Gladstone, until her death in 1894. For details as to her religious services the inquirer should consult Lady St. Helier's Memories of Fifty Years. With regard to Gibbon Dr. MacLaurin asks on p. 187 whether the cause of his death was not acute septic peritonitis from the bursting of the septic hydrocele and hernia through the inguinal ring. It is, of course, possible that this happened, but there is no note of acute abdominal peritonitis in the official account of the post mortem. The contents of the sac were inflamed: "In omento et in intestino colo haud dubia recentis inflammationis signa vidimus." But the surgeon continues that when the abdomen was opened the stomach was found much displaced downwards, the liver was covered with small tubercles, and the gall-bladder distended. "In caeteris visceribus . . . . nulla morbi vestigia extiterunt." Other of Dr. MacLaurin's papers deal with Anne Boleyn, Charles V., Don John of Austria, and Marat. Altogether lovers of literature will be grateful to Dr. MacLaurin, and we hope to be able to welcome another work from his pen before long, only we advise him to take to heart the advice of Dr. Routh and "verify his references"; Cicero (p. 254) may have said "Video meliora proboque, deteriora sequor," but the remark is generally attributed to Ovid; Metamorph. VII., 20–21.

TRAITÉ D'OPHTALMOLOGIE.

By Dr. A. POULARD. In two volumes, with 710 illustrations and 3 coloured plates. Paris: Masson et Cie. 1923. Pp. 1457. Fr.120.

THIS work has the merit of being original in the sense that it does not slavishly follow the pattern of previous text-books. Instead of the usual preliminary chapters on the anatomy and physiology of the eye, an adequate knowledge of these things is taken for granted, and the book begins with a chapter on surgical technique with directions for sterilising, &c., and for administering local anæsthesia. After a second short chapter on methods of diagnosis, we are taken through the ordinary routine of ocular diseases in a way not very different from that of other text-books, the descriptions being greatly assisted by excellent illustrations. These are especially welcome in the sections dealing with operations. Dealing with wounds of the eyeball, the author deprecates the excessive dread of sympathetic ophthalmia, a dread which in his view is responsible for many unnecessary mutilations. He is opposed to the total enucleation of a wounded eye except in very special circumstances, and would in most cases substitute a partial evacuation with retention of the outer envelope or even of the whole posterior portion of the globe. So long as the ciliary body is removed there can, he says, be no danger. The probability is that in this he is right. Yet in view of the tragic consequences which have sometimes followed a too conservative procedure, most surgeons will still choose to be on the safe side, even at the sacrifice of some cosmetic advantage. The description of the major operations proceeds along accustomed lines, but operations on the lids are described and illustrated in greater detail than is usual. We must demur to the advocacy of probing with large probes for lacrymal obstruction. This treatment was formerly common in this country but has been very generally given up on account of the frequency with which false passages were made and the formation of secondary scar tissue caused. According to Poulard, excision of the sac is an operation only rarely required in cases where probing has proved ineffectual. We look in vain for a recognition of the danger of infection to the cornea in operation cases or of the fact that a common cause of hypopyon ulcer is regurgitation from a chronically inflamed sac. There are certain other omissions. The author justly criticises the use of the phrase "rheumatic iritis" for cases of iritis where the cause cannot be determined, but he fails to point out the different septic conditions which have been shown to have a causal relation to many of these cases. Again, in treating of ocular paralysis he justly remarks that cases attributed to cold are generally those in which the real cause is unknown, but he does not afford much help in arriving at a more exact diagnosis. Multiple sclerosis is only just mentioned as a possible cause.

The work is well written, well printed, and well illustrated, but it is not a text-book likely to supplant those already popular with English-speaking students.

MONTAIGNE AND MEDICINE.

By JAMES SPOTTISWOODE TAYLOR, M.D. Lond., Commander, Medical Corps, U.S. Navy. Oxford University Press: Humphrey Milford. Pp. 244. 14*s.*

THIS book is a reprint of a series of papers which we have noticed from time to time, as they appeared in "Annals of Medical History," Vol. III., Nos. 2, 3, and 4, published in November, 1922. In book form many additional illustrations have been supplied. Montaigne is one of those discursive and personal writers to whose works, as to those of Sir Thomas Browne, Feltham of the "Resolves," Burton, and Montagu, who wrote "Manchester al Mondo," we return again and again, and Commander Taylor here puts before his readers in a handy form Montaigne's comments on contemporary medicine and physicians, his thoughts on matters of life and death, an account of his ailments (he suffered much from urinary calculi), and his travels in search of health, all these excerpts being interspersed with shrewd comments of his own. We think that Commander Taylor has rather strained the likeness between Montaigne and physicians; when we read his comparisons we cannot help remembering that "there is a river in Macedon, and there is also moreover a river at Monmouth . . . . and there is salmons in both." We draw attention to this with the less reserve in that Commander Taylor himself seems to doubt what he calls "perhaps superficial parallelisms and analogies." However, he has produced a most interesting book for which we are grateful. We may note modern parallel to Montaigne's account of the Flagellants whom he saw in Rome. On p. 174 Commander Taylor quotes from his account of how the penitents scourged themselves with ropes until their backs were raw and bloody, and he was struck with their apparent indifference to pain. The same scene may be witnessed in Persia to-day at the Moharram festival where the devotees scourge themselves with heavy chains until the back and shoulders are a mass of bloody bruises, while others slice their heads with swords until the blood streams down over the long white shirts which they wear.

Encyclopédie Française d'Urologie.

Edited by Dr. A. Pousson, Professeur à la Faculté de Médecine de Bordeaux, and Dr. E. Desnos, Secrétaire Général de la Société International d'Urologie. Paris: Octave Doin. 1922. Vols. V., pp. 1110, and VI., pp. 1086. Each vol. Fr.60. Vols. I.–VI. complete Fr.300.

These two compendious volumes form parts of an important work on urology by various French authors. The scheme of the work is encyclopædic. The literature of each subject is collated, and a very extensive classified bibliography is added at the end of each chapter. The views and methods of many authorities are concisely given without interfering unduly with the thread of the narrative. Vol. V. is entirely devoted to diseases of the urethra. Among many important articles may be noted examination of the urethra and urethroscopy by Nogués and Papin, some excellent coloured illustrations being included in this article. Stricture of the urethra and its complications is described in 215 pages by Escat, and further space is devoted to the technique of operations on the urethra by Nogués, Heitz Boyer, and Genouville. Vol. VI. deals entirely with diseases of the prostate and urinary symptoms in general. There are chapters on the examination and injuries of the prostate (André), inflammation, calculi and cysts (Oraison), hypertrophy (Marion), malignant tumours (Pauchet), tuberculosis (Erzbishoff). The extent and thoroughness of the work may be gauged by the fact that the article on hypertrophy of the prostate by Marion extends to 187 closely printed pages, with an additional 16 pages for the bibliography. In this section the author gives an account of the present knowledge of simple enlargement of the prostate and its treatment. In another section he describes the operative technique he personally adopts. The section on urinary symptoms includes such mechanical conditions as retention and incontinence of urine (Delbet), and abnormal conditions of the urinary secretion and composition, such as anuria, phosphaturia, oxaluria, glycosuria, &c.

It is impossible to discuss the various subjects in detail, but it may be said that the thoroughness with which the literature is collated and the high standard of the discussion are maintained throughout. These volumes form, with the others which have already appeared, one of the most extensive and authoritative publications on urology at the present time. They should be included in the reference library of every urinary surgeon and may be recommended to the notice of physicians studying the medical aspects of urinary disease.

Poisonous Plants of All Countries.

Second edition. By A. Bernhard-Smith, L.M.M.S.A. London: Baillière, Tindall and Cox. 1923. Pp. 112. 6*s*.

This book consists of a list of the known poisonous plants. Of each plant, the nationality, popular synonyms, the natural order, the chief characteristics and season of flowering, and the toxic principles are given. Then follow a few lines from one of the poets—some apt, some of doubtful suitability. A small illustration is given of nearly all the 150 plants named.

The value of the book is as one of reference, an intermediary between a work on botany and one on toxicology. It would be more compact and would bear a more business-like air if the quotations were omitted. Some lines on the relative toxicity of the plants would please its readers more than lines of poetry. The appendix with lists of "plants reputed poisonous" is especially tantalising, as one gets no clue as to whether the reputation is true or false. The illustrations, uncoloured and small, are quite good for their size, but are not sufficiently detailed to help much in the recognition of the plants. Some of the active principles given do not correspond in title to those accepted by pharmacologists—scillipiain is given for squill, rheonilic acid for rhubarb; laburnum and its poison are given as cystisus, and cystisine instead of cytisus and cytisine. The plants are divided into classes according to the action of their poisonous constituent—namely, those acting on brain, spinal cord, and heart, irritant poisons, and specific irritants. These last include micro-fungi and bacteria. As, however, symptoms are not given, this division does not carry much value. The book may be useful in putting the reader on the track of any poisonous plant he wishes to study, but he will not find much of value about the plants in its pages.

Differential Diagnosis of Internal Diseases.

By M. Howard Fussell, M.D., Professor of Applied Therapeutics at the University of Pennsylvania; Physician to the Hospital of the University of Pennsylvania. London and New York: D. Appleton and Co. 1923. Pp. 880. 35*s*.

This is a reprint of a popular volume by the late Prof. Fussell. It follows the classification of diseases used in Osler's Text-book, and deals at length with the differential diagnosis in each case. Certain omissions, such as the similarity of gastric syphilis and carcinoma of the stomach, and the importance of cardiac and renal diseases in the differential diagnosis of ascites, call for correction, but the volume as a whole is a well-arranged and useful one. As a work of reference for the general practitioner it should be welcome.

Accidents du Travail.

Guide pour l'évaluation des incapacités. Second edition. Par Léon Imbert, C. Oddo, P. Chavernac. Paris: Masson et Cie. 1923. Pp. 936. Fr.40.

This book is primarily written for those who have medico-legal responsibilities connected with the French law of 1898 et seq., to facilitate the consideration of problems arising in connexion with industrial accidents and occupational diseases. The authors have written lucidly in their several sections; for medical men information is given as to the bases of legislation and jurisprudence in relation to the results and sequelæ of accidents. For the legal profession essential medical information is provided and expressed in language free, so far as is possible, of technical medical terms.

This second edition is entirely re-written and, in fact, constitutes almost a new work. New and unlooked for problems have arisen, many of them consequent on the recent war. The ground covered is extensive. Industrial sickness and its development; traumatism in relation to the incidence (post-traumatic) of tuberculosis, cancer, and general disease; the traumatic chronic arthopathies; the chronic œdemas, thrombophlebitis of the limbs; regional injuries, including the eye, ear, and central nervous system; traumatism in relation to the genito-urinary system (male and female); psychoneuroses in relation to industrial accidents are among the subjects dealt with. The views of the authors may not be accepted in every detail, but they have ventilated in a provocative and able manner problems that are of considerable and sometimes pressing importance.

An appreciable number of ex-Service men in our own country have developed pulmonary tuberculosis after their disabilities of gunshot wounds or traumatic injuries of the chest or chest wall. The lapse of time in some cases between the original injury and the overt symptoms or signs of tuberculosis may cover several years, and it is then difficult to link up the new infection as having relation to the original disability. The authors state that it is recognised that traumatism may, in certain cases, be the means of inoculating or localising tubercle; of aggravating or revealing existing or latent tuberculosis. In rare cases an accident may cause a generalisation of pre-existing tubercle. War experience has, in their opinion, to a large extent, confirmed the fact that severe and extensive injuries are not found to be followed by tuberculosis nearly so frequently as when the injuries have provoked less severe reactions. Sergent, Challamel, Léon Bernard are quoted, and the consensus of opinion suggests that penetrating wounds of the chest, producing comparatively little immediate effects, may several years later be the starting-point of pulmonary tubercle. As to traumatic nephritis, traumatism is stated to produce in a previously healthy kidney lesions which in their chronic character and by their extension to the other kidney are clinically akin to Bright's disease and may be confounded with it. The difficulties and problems raised in accepting this condition as a new disease entity are appreciated and discussed. The volume, though somewhat bulky, is worthy of careful perusal.

Hodgkin's Disease.

By R. A. Bennett, M.D. Lond., M.R.C.P. Bristol: John Wright and Sons. 1923. Pp. 56. 2*s*.

In this pamphlet the author gives an excellent straightforward account of Hodgkin's disease based on his own experience of 15 cases and covering much the same ground as the articles on the subject in the larger systems of medicine. The author has no particular fresh view to bring forward, but in an open-minded discussion of the causation of the disease he inclines to the view that it is due to tubercle bacilli which have been altered by the lipolytic ferment of lymphocytes operating in individuals of a peculiar disposition. As an empirical trick for controlling the bouts of fever, he commends the inunction of creosote (½ drachm) in the axilla or groin.

Books for Nurses.

Pocket Cyclopædia of Nursing. First edition. Edited by R. J. E. Scott, M.A., B.C.L., M.D. New York: The Macmillan Company. 1923. Pp. 746. 14*s*.

This pocket cyclopædia of nursing comes at a time when the trained nurse and the nurse in training, anticipating examinations by the State, feel a special need for some handy book of reference in addition to the general text-book. The contributors to this excellent cyclopædia include 13 American registered nurses, so that the nurses' needs have been supplied by those who appreciate from practical experience their point of view. All subjects are alphabetically arranged, and the use of a large number of cross references takes the place of a general index. This cyclopædia should be popular, supplying as it does just the information which is often sought vainly in a dictionary. The information given is by no means superficial, but has been well chosen, and in cases of disease not only is there a lucid explanation given, but a description of the nursing care and treatment follows. Six excellent pages are devoted to diabetes mellitus, and valuable references made to the psychoneuroses. A number of illustrations are included.

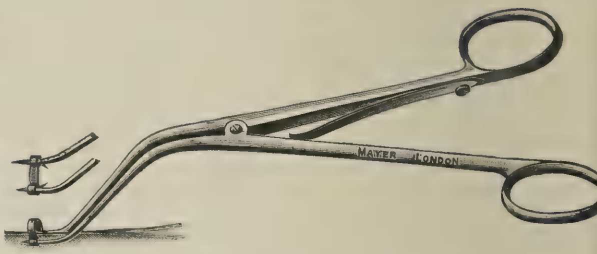
Principles of Home Nursing. By E. L. Mohs, R.N., A.B. London and Philadelphia: W. B. Saunders Company. 1923. Pp. 307. 10*s*.

Miss Mohs has written a book full of useful information, but a book more suitable for the trained nurse or the nurse in training than for the lay mind interested in home nursing. There is an exhaustive chapter on bacteriology with detailed directions as to the use of the microscope for the observation of bacteria and the technique employed in making throat cultures. The "home nurse" in this country would neither be expected to have an extensive knowledge of bacteriology nor would she be called upon to take throat cultures, reduce a dislocated jaw, or to understand the sphygmomanometer. The title of this book is misleading, unless it was intended to imply that it contained information necessary for the trained nurse in the home.

New Inventions.

SUTURE REMOVING FORCEPS.

The usual methods of removing Michel Clips have great disadvantages. In one the under blade of a special pair of forceps has to be forced up against the actual wound, and in the other, where two hooks are used, the method is clumsy and the hooks are not easy to manipulate. I have therefore had made a pair of forceps angled twice on the flat with two points instead of blades, one point being 1/16 in. longer than the other. These points are separated by closing the handles and are normally held together by a strong spring. The method of use is to insert the longer point into an eye of the clip, and while this point is steadied the shorter one can easily be fitted into the other eye. The handles are then closed and the clip is stretched out flat, being then easily removed. There is no discomfort to the patient and the forceps are very easy to use.

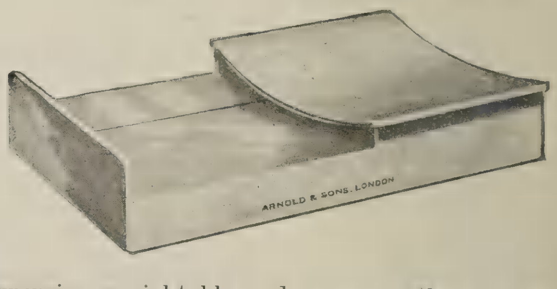


Messrs. Mayer and Phelps, Chiron House, New Cavendish-street, are the manufacturers of the instrument.

Shrewsbury. Frank H. Edwards, M.B., M.R.C.S.

COMBINED IRRIGATION TRAY AND PELVIC REST.

The combined irrigation tray and pelvic rest, here illustrated, is a convenience to the surgeon as it enables him to use a cystoscope, or any other irrigating bladder or urethral instrument on an ordinary consulting room couch, or theatre operating table. It does away with the necessity for an expensive special table, and overcomes the objections (instability—splashing of couch and towels) which arise from the use of a makeshift, such as a sandbag and separate tray or kidney basin. With the back of the consulting-room couch raised, the tray can be used for urethral irrigation with the patient in a sitting or reclining posture, with the couch flat it gives the necessary pelvic elevation for a cystoscopic examination.



The apparatus, which is strongly made to carry a stout patient, and finished in white enamel, has been made for me by Messrs. Arnold and Sons, of 50/52, Wigmore-street, W.

Sheffield. Thos. B. Mouat, F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 22, 1923.

THE STATE OF PUBLIC HEALTH.

THE Annual Report[1] of the Chief Medical Officer of the Ministry of Health for 1922 is a voluminous but closely-written document and should be in the hands of every public man and woman, for the right conduct of national health is alike a matter of the gravest and most general concern. The Report commences by giving the statistics illustrating the state of public health in England for the year 1922, and the figures show that, while great gains have been made recently in the health of the nation, and while the death-rate is declining and the expectation of life growing longer, there remain certain places in which the mortality has grown more serious and the position demands inquiry. The number of births registered in 1922 show a decline, while the death-rate is slightly higher than in the previous two years, but nevertheless the expectation of life at birth in this country, as indicated by the figures, is 11 years longer for males and 13 years longer for females than it was 60 years ago. That is the kind of generality which means a great deal when its import is realised. The infantile mortality rate is the lowest yet recorded in the country, although admittedly there is much unnecessary loss of life both for mother and infant in the first month of infancy, while the figures in respect of epidemic infectious diseases give no common message. Measles, pneumonia, and scarlet fever present high notification figures, but diphtheria, enteric, cerebro-spinal fever, encephalitis, and tuberculosis indicate a decline of incidence. Of the two great non-notifiable diseases, venereal disease and cancer, the broad deduction from the facts and figures seems to be that venereal disease has declined and that cancer has substantially increased. The disturbing position with regard to cancer is made the subject of detailed treatment, and those who talk glibly about the supineness of science in the face of a mortal scourge would do well to read closely this section of the Report, if only to ascertain how much work is being done, for how long a period much of it has been carried on, and how valuable is the information which has already been obtained. The Cancer Committee of the Ministry is engaged in a number of inquiries, statistical, nutritional, and epidemiological, and has as one of its principal objects the coördination of investigation in this country and abroad. Happily several organisations have for many years been occupied with this subject, and the accomplishments of the Cancer Department of the Middlesex Hospital, the Imperial Cancer Research Fund, the Cancer Hospital in Fulham-road, and the Radium Institute will be taken into consideration, as well as the work done in various places under the auspices of the Medical Research Council. In May of the present year the British Empire Cancer Campaign was initiated to make a wider appeal for public financial support in the common struggle against cancer, and it would be unreasonable to suppose that nothing more will come of such varied and intensive activities, though in our ignorance of causal agencies no one can prophesy the rate of progress.

A long and interesting section is that dealing with the relation of food to health and disease, in which the questions of the inspection of meat, the sale of food and drugs, the grading of milk, and the general safeguards of our food-supply are gone into. The section is illustrated by a summary of inquiries into cases of food poisoning which occurred during the year, several of the examples given, like that of the outbreak of botulism in Loch Maree, having been fully reported in our own columns. An adequate supply of wholesome food is one of the most important factors in the production and maintenance of national health and efficiency and, as Sir GEORGE NEWMAN points out, this was abundantly proved during the European war, when it was found that the soldier could withstand without detriment to health all manner of hardships and exposures so long as he was regularly provided with sufficient and suitable food. We recommend for serious attention the advice given for the protection of the consumer against food poisoning, for it has not been considered sufficient to supply such general statements as that the premises should be clean, that materials should be of good quality and be properly stored, and that throughout distribution care should be exercised of the finest, and so on. The health and cleanliness of the worker is introduced as a factor of the first importance in the following words: "Whatever is permissible in other industries, the only satisfactory arrangement in respect of food is that it should be prepared by persons entirely free from any communicable or infectious disease, local or general. Such a condition demands (*a*) careful selection and adequate medical supervision of the workers; (*b*) strict cleanliness of person and clothing, which means facilities for washing and suitable clean overalls; and (*c*) the special supervision of healthy workers who have been in contact with cases of disease ('contacts') or carry infection without suffering from disease ('carriers').' It is now the duty of all local authorities to notify the Ministry promptly on the occurrence of food poisoning, and we may say here that that duty is shared by the consumer. Information should be given by the public to the medical officer of health when there is any suspicion that food poisoning has occurred, for only in this way can, on the one hand, abuses be detected promptly, and, on the other, foolish alarms be avoided. Before now the inadvertent creation of food scares has produced an attitude in regard to food poisoning whose influence on the health of the nation as a whole may have been more serious than that of the particular outbreak of poisoning itself.

Throughout the Report there runs the general message which is repeated in so many words in Sir GEORGE NEWMAN'S concluding observations—wise government depends on the assent of the governed. Members of the public are under obligations to cultivate their own health and capacity and so to conduct themselves as not to conduce to the hurt or risk of their neighbours. Preventive medicine is what we have to look for in the future, and its progress must depend in high degree upon the enlightenment of the people.

CANCER AND DIET.

MOST medical men will have been startled to find in their morning papers last Saturday headlines announcing in more or less flamboyant terms a great discovery in the treatment of cancer by diet, communicated to the meeting of the British Association in Liverpool by Dr. S. MONCKTON COPEMAN. Sensational statements on medical subjects which appear in the daily press do not often demand comment from us, but in this instance weight is given to the statements by Dr. COPEMAN'S standing as a public man and one to whom preventive medicine is substantially in debt. On the basis of the newspaper reports Dr. COPEMAN is apparently of opinion that vitamin A, while of great importance to the young and growing organism, is of comparatively little importance to the adult. Now the effect of rationing during the war years, especially in the Central European States, was essentially a rationing in those foods, such as butter and milk, which in a normal dietary provide the fat-soluble vitamin A, and the disastrous effects of this experiment on a large scale do not bear out Dr. COPEMAN'S contention, which does not seem to be based on any original investigation of his own. In papers[1] [2] published two years ago in our columns the workers from the Lister Institute attributed the hunger-osteomalacia which occurred in Vienna in 1920 to a fat-soluble A deficiency. They also showed that the disease affected chiefly middle-aged and old people of both sexes. Moreover, Dr. COPEMAN seems to have overlooked the literature on the subject. In 1919 Prof. J. C. DRUMMOND[3] undertook an experimental investigation designed especially to test this very point, and he concluded that the adult animal organism requires a regular supply of vitamin A, although the daily requirement is of a smaller order than that necessary to ensure growth in a young animal. Prof. DRUMMOND states that "there is every reason that great care should be taken to ensure that dietaries of adults contain an adequate supply of foodstuffs in which fat-soluble A is present.... In the absence of this factor the resistance to diseases of bacterial origin is seriously impaired." The statement by Dr. COPEMAN that an excess of vitamin A in the diet might eventually become injurious is contrary to all available experimental evidence.

It is difficult to understand the rationale of Dr. COPEMAN'S diet. It is not a vegetarian diet, for he allows ham and bacon. Were his premises correct, then the restriction of vitamin A, which is a factor necessary for the growth of a young animal, should have a retarding effect on the growth of cancer. But the diet actually recommended by Dr. COPEMAN is not a diet free from this factor. He excludes animal fats containing vitamin A such as butter, eggs, and cream, but he adds lettuce and watercress which, as he himself states, contain fat-soluble A. On the basis of his own arguments there is no reason why such a diet should have any effect on the growth of cancer, unless he presumes, as he appears to do, that an amount of vitamin A insufficient to maintain the growth of cancer cells is adequate to maintain the well-being of the patient. But here again experimental evidence has been adduced to show that the growth of cancer cells proceeds quite independently of the presence or absence of vitamin A. Prof. DRUMMOND[4] demonstrated in 1917 that the growth of cancer cells in rats is not inhibited by the complete absence of the fat-soluble vitamin A, and that, in fact, it is not possible to bring about an inhibition of tumour growth by employment of any dietetic restrictions without the nutrition of the host becoming seriously impaired. More recently work in the laboratories of the Imperial Cancer Research Fund has led to exactly the same conclusion.[5] In 1922 we published a paper by Dr. STANLEY WYARD[6] in which he reported on the results obtained in cancer patients by placing them on a diet deficient in vitamin A. This was done at the suggestion of Dr. COPEMAN himself, who was responsible for the composition of the diet. Dr. WYARD'S conclusion was that the results were entirely negative. The diet now adopted by Dr. COPEMAN differs from that which he recommended to Dr. WYARD in containing more vitamin A. It is difficult to gather what claims Dr. COPEMAN now makes for this new diet. It is said to alleviate pain. But the dismal history of cancer remedies shows that this claim is made for every remedy that has failed in other respects. He also claims an increased expectation of life. From the reports published in the press it is impossible to see how Dr. COPEMAN justifies this claim. How many cases has he had under observation? Has he selected his cases or has he chosen his cases indiscriminately? And how does he calculate the expectation of life of a patient afflicted with cancer and not undergoing his treatment?

Dr. COPEMAN may complain that we are criticising his statements on incomplete reports. But it is these reports which have been laid before a lay audience and circulated widely in the press, and their details have not been submitted to the judgment and criticism of his peers. Dr. COPEMAN is a member of the Departmental Cancer Committee, appointed by the Ministry of Health under the chairmanship of Sir GEORGE NEWMAN, which has recently issued an excellent memorandum on the whole cancer problem. The omission from this memorandum of any reference to the effect of diet on the treatment of cancer suggests that Dr. COPEMAN has been unable to convince his colleagues and has now appealed to a wider though less critical audience.

◆

THE KITCHENER MEMORIAL MEDICAL SCHOOL.

Lord KITCHENER on the occasion of his last visit to the Sudan expressed a strong wish that there should be a medical training school for Sudanese students at Khartoum, and no more suitable memorial for the great soldier could have been chosen than to found such an institution. The proposal appealed to the Sudanese Arabs as well as to KITCHENER'S own countrymen, and as a matter of fact of the £13,000 which had been subscribed by the end of last year, all but £2000 came from the natives of the Sudan, while in addition one Sudan merchant has handed over all his property to trustees in order that on his death the income, which will amount to some £1200 a year, may be devoted to the maintenance of the medical students. There is pressing need for this medical training school in order that young Sudanese doctors may work under Government supervision to bring assistance to the inhabitants of vast districts which are fever-ridden or subject to epidemic and endemic attacks of a dangerous and sometimes decimating character. In addition to malaria, tuberculosis, dysentery, enteric fever, small-pox, and syphilis, there remain to be treated sleeping sickness, kala-azar, bilharziasis, elephantiasis and leprosy, ankylostomiasis and ophthalmia, and the Government of the Sudan is quite unable to deal with the medical and sanitary needs of the immense areas unless a staff of medical men can be established, inured to the climate and familiar with the customs of the people.

[5] Nineteenth Annual Report of the Imperial Cancer Research Fund, 1922.

[6] S. Wyard: THE LANCET, 1922, i., 840.

The experience of Khartoum Civil Hospital in the case of a few selected youths has shown that the Sudanese Arabs can be trained to be useful medical assistants, and in April of last year, although sufficient funds had not been raised, it was decided to commence the medical school buildings. The immediate object is to give a four years' period of instruction to 12 selected young men each year. The proposed curriculum allots two years to pure and applied science and two years to medicine, surgery, midwifery, and hygiene, out-patient attendance being required for the last three years; a diploma will be conferred on successful candidates, practice being limited to the Sudan and based on certain specified conditions. This is the method by which it is designed to obtain a corps of conscientious assistants, accurately trained up to a definite standard, but as soon as the immediate need for doctors has been met in this way, and a suitable teaching staff has been built up, it is proposed to extend the length of the medical course and to bring the curriculum up to the standard demanded by European medical schools. The most promising of the medical assistants will be referred back to complete this fuller course, in addition to other selected youths from the Gordon Memorial College, Khartoum, who would have received preliminary scientific instruction. For the medical school will be an integral part of the Gordon Memorial College, and the trustees and executive committee of that College are being asked to act for the school.

The expenditure involved by the immediate scheme is modest, but substantial, and the money is urgently required that the project, while under weigh, may be completed without delay and its consequent embarrassments. All capital expenditure up to now has been met, and £20,000 remain towards the endowment fund. The close estimates of annual expenditure show that £3000 per annum will be required, to provide for which an endowment fund of £60,000 is needed, but this amount has already been reduced by substantial sums; £40,000 at any rate is still required at once. Owing to the Government being prepared to lend the services of its scientific and medical staff during the initial years of the enterprise, to carry out the teaching in addition to their other duties, the expenditure in this direction is extraordinarily small, while the school is fortunate in that the Wellcome Tropical Research Laboratories are installed in the Gordon College a short distance from the medical school, and the director of these Laboratories will assist in the scientific and medical teaching. If, as all believe, those who help themselves are the people who deserve to be helped, the claim of the Sudanese is a strong one. The natives showed the greatest loyalty throughout the war, they contributed over £34,000 to the Red Cross Fund, and, as has been said, the first £13,000 subscribed in the Sudan for the medical school buildings was for the most part given by the natives of the country. The need then is real and urgent; the work has been begun with confidence in the strength of the appeal; those most directly interested have done their utmost to forward the movement; and the sum asked for is small. In these circumstances we hope that those responsible for the Kitchener Memorial Medical School will have their anxiety with regard to money speedily removed.

◆

WE understand that the British Red Cross Society is in close touch with the Japanese Embassy in London, and is working in conjunction with a committee formed at the Japanese Embassy, with a view to providing assistance for Japan. So far the question of sending personnel to that country has not arisen. Present information goes to show that what is required is food and clothing, and it is not considered likely that doctors and nurses will be sent out unless a definite appeal to do so is received from the Japanese Red Cross.

Annotations.

"Ne quid nimis"

THE HOSPITAL ALMONER AND SOCIAL SERVICE.

WHEN Florence Nightingale went to the Crimea she found that it was impossible to apply medical treatment without at the same time attending to the more personal and economic wants of her patients. "The fact is," she wrote to Sidney Herbert, "I am now clothing the British Army." The social service work of the present-day hospitals is an outcome of precisely this same necessity, and although the almoners' departments of the voluntary hospitals have always modestly avoided the limelight, an ever-increasing need continues to develop this side of our voluntary hospital system. In this work St. Thomas's Hospital blazed the trail during the pioneer days when vicarious charity was blindly attempting to deal with an impossible problem. Starting in 1905 as a Social Service Office in connexion with the Casualty Department, the almoner's work has steadily increased until the St. Thomas's office deals with 16,000 inquiries in one year, and raises more than £5000 apart from invested income; and there would seem to be every prospect of social service work of all kinds increasing as time goes on. In these days the raison d'être is not far to seek. Few patients present themselves for treatment at hospital who have not got some economic problem the solution of which is intimately related to the cure of their illness. Physician, nurse, and almoner are interdependent. As a good example of this question the latest St. Thomas's report[1] states that during the last seven months of 1922, 295 children were recommended by the out-patient surgical staff for operation for enlarged tonsils and adenoids. Before operation the homes of these cases were all visited by the almoner, and it was found that 200 had homes where the children could receive simple post-operative treatment, whilst 95 had to be admitted to the wards on account of unsatisfactory home conditions. Amongst those refused were found children who, after operation, would have had to share a bed with two or even three other children, or would have had no proper bed at all. In the report of the almoner of the Royal London Ophthalmic Hospital, Moorfields,[2] the value of such inquiries is again emphasised, especially in cases of ophthalmia neonatorum, where every effort, economic and medical, must be made to prevent permanent blindness.

The following up of cases which have been discharged from hospital is yet another service falling to the lot of the social service departments. Both the St. Thomas's and the Moorfields reports show how necessary this task may be in the case of blind patients, for whom suitable employment, on leaving hospital, is often difficult to find. The Moorfields report points out that the giving of small sums of money will not solve the problem of the future for a man who is going blind; he must probably face a year or two of straitened circumstances whilst he is learning a suitable trade, and it is during this period that sympathetic backing from the hospital means everything to him. Some day, perhaps, we shall see established in London a special employment bureau which will concern itself entirely with the welfare of those discharged hospital patients who are only fit for certain occupations and can only work under favourable conditions. Such an invalid employment bureau is greatly needed, but it would require the utmost sympathetic coöperation on the part of employers, trade unions, doctors, and social service workers. Probably only those who work in the departments concerned realise the work that is done by the almoner's office in bridging the gap between the voluntary hospitals and the various State grants. Hospital departments dealing with school-children, pensioners, and tuberculous patients, venereal disease clinics with their hostels and after-care work, maternity and child-welfare centres all find in the almoner a connecting link. It is true, of course, that patients will from time to time abuse the voluntary hospital system by concealing their financial position, but the St. Thomas's report places it on record that on the whole "patients are amazingly honest in their dealings with the hospital, and are apt quite as often to omit some liability, such as the support of an aged parent, as to conceal some source of income." The almoner, in fact, touches life at many points and in all her dealings the aim is not to pauperise but to help patients to help themselves, not to demoralise but to assist these victims of adverse circumstances to develop their own personalities under the stress of difficulties and hard times.

SYMBIOSIS.

SOMEONE has said profoundly that dirt is matter in the wrong place, and the aphorism has been accepted as condensing in a phrase the valuable lesson that much that in some circumstance appears to be merely repellent may in other circumstances be highly beneficent. The discovery of the agencies by which symbiosis is carried on in animals and plants goes one step further in showing that two things may be associated together in conditions hardly distinguishable from parasitism, the partnership being necessary to insure their joint lives, while the word parasitism generally implies mischief to the host. The bacteroids in the nodules of leguminous plants fix the atmospheric nitrogen, and thereby render that nitrogen available for assimilation by the plants; that is a simple example of symbiosis where the micro-organisms carry on necessary work for a common life. Prof. Nuttall, the Quick Professor and Director of the Molteno Institute for Research in Parasitology at the University of Cambridge, made symbiosis the subject of his presidential address at the British Medical Association, and gave many interesting examples of the process in plants, animals, and insects. The subject has been much worked upon recently, and is of interest equally to the physiologist, the pathologist, and the parasitologist. It may easily be imagined that the investigation of the various problems is fraught with difficulties, and sometimes conclusions as to the interrelations of the various bodies cannot yet be arrived at, but Prof. Nuttall concludes that further discoveries are approaching, and that a wide field of fruitful research is open to those British workers who enter upon it

BLOOD PRESSURE IN THE NEW-BORN.

IN a recent communication to the Chicago Gynecological Society, Dr. Ralph A. Reis and Dr. Arthur J. Chaloupka[1] described their observations at the maternity of the Michael Reese Hospital, Chicago, on the blood pressure of 100 new-born infants following normal and pathological labour. The readings were all taken with a mercury manometer and an arm band 6 cm. wide. It was found that the average systolic blood pressure during the first day of life in 55 full-term infants following normal spontaneous labour was 43 mm. Hg, the minimum record being 32 and the maximum 58 mm. There was a gradual daily increase in the blood pressure until, on the tenth day, beyond which, owing to the mothers' discharge from hospital, the observations were not continued, the average reading was 78 mm. The greatest rise was during the first three days, the reading being 59 mm. on the fourth day. As a general rule, the blood pressure was higher in heavy infants. The sex of the infant, the presence or absence of jaundice or fever, the pulse-rate, and caput succedaneum appeared to have no effect upon the blood pressure. Low readings were met with in premature infants and twins proportionate to the birth weight and prematurity, while the greatest increase in blood pressure was shown after midplane forceps extraction and version extraction, and lesser increases after low forceps extraction, relatively dry labours, prolonged second stages, and in infants with large cephalic measurements. The increased blood pressure in all these cases appeared to be due directly to increased trauma to the fœtal head. With clinical improvement the blood-pressure readings gradually approached the normal.

CONGENITAL MIOSIS.

EXTREME contraction of the pupils, apart from the effects of iritis, is generally the result either of spinal disease or of drugs. An instance is recorded in the September number of the *British Journal of Ophthalmology*, by S. Holth of Christiania, where it was due to neither of these causes but was present as a family affection in two sisters and a brother, in each case the condition being permanent, having been noted in two of them as unchanged after an interval of more than 20 years. All three had pupils of about 0·5 mm. diameter, which, after the instillation of mydriatics, never dilated further than 2·5 mm. In one of the sisters the condition was associated with spasm of accommodation, but in the other two cases it was not. The interest of this observation lies in its affording a new instance of family inheritance. The parents were first cousins and the father, who was only seen once, was noted to have rather small pupils, 2·5 mm. in diameter. Two of the affected members died and their eyes were obtained for pathological examination. The anatomical explanation of the condition was pronounced to be the defective development of the dilator muscular fibres of the iris. As to this it might be objected that the dilator muscle of the iris is normally so slight in development that for many years its existence was doubted. On the other hand, the persistence of partial miosis after the use of mydriatics and the permanent nature of the condition negatives the idea that spasm of the contractor muscle can have been the cause, and an affection of the sympathetic was excluded by the instillation of cocaine which enlarged the palpebral fissure while having no effect on the pupil. The only symptom complained of was a certain degree of night blindness owing to the defect of normal dilatation of the pupil in the dark. Two of the three patients were myopic and in their case the daily use of atropine or hyoscine was found to be a sufficient treatment. In the case of a patient who is not a myope, a small optical iridectomy would appear to be indicated.

THE WASSERMANN REACTION IN LEPROSY.

Major R. B. Lloyd, Dr. E. Muir, and Mr. G. C. Mitra,[1] of the School of Tropical Medicine, Calcutta, examined the Wassermann reaction in a series of 286 unselected cases of undoubted leprosy, consisting of 228 adults and 58 children. The adult cases came from the leper asylums of Gobra and Allahabad, and from the out-patient department of the Calcutta School of Tropical Medicine, and the children from the Purulin Leper Asylum. Each blood was tested with three separate antigens—viz., (1) a cholesterinised alcoholic antigen, (2) Noguchi's antigen, and (3) Bordet's antigen, to which 0·4 per cent. of cholesterin was added. Among the adult patients a positive reaction was found in 41·7 per cent. of all cases, in 27 per cent. of the anæsthetic cases, in 47·4 per cent. of the mixed cases, and in 63 per cent. of the nodular cases. Among the children the figures were much higher, a positive reaction being found in 62 per cent. of all cases, in 47 per cent. of the anæsthetic cases, in 80 per cent. of the mixed cases, and in 100 per cent. of the nodular cases. The possible influence of syphilis in causing the positive reactions was investigated by careful inquiry and examination, which elicited evidence of a previous venereal sore in 49 of the adult cases, but of these 15 gave a negative reaction. If it be assumed that the remaining 34 positive reactions were due to syphilis and not to leprosy, this would indicate a syphilitic rate of 14 per cent., which is about the average syphilis rate of the population. Among the children only four showed lesions suggestive of inherited syphilis, and among these the Wassermann reaction was positive in one case, partially positive in one case, and negative in two cases. On the other hand, a control series of 46 untainted children yielded positive reactions in eight cases, or 17 per cent., which, though not inconsiderable, was within the syphilis rate, and was in striking contrast with the high percentage in the leper children.

[1] Indian Journal of Medical Research, July, 1923.

A VISIT TO MEDICAL SCHOOLS IN CANADA AND THE UNITED STATES.

IN the early part of this year Mr. A. E. Webb-Johnson, surgeon to the Middlesex Hospital and dean of the Medical School, visited the principal hospitals and medical schools of Canada and the United States, the itinerary including Quebec, Montreal, Ottawa, Toronto, Boston, New York, Philadelphia, Baltimore, Washington, Cleveland, Chicago, and Rochester. Mr. Webb-Johnson's observations and experiences, communicated to Mr. S. G. Asher, chairman of the Council of the Medical School, and now circulated privately, form a useful contribution to the study of hospital administration. Visiting the Rockefeller Foundation, Mr. Webb-Johnson found the directors committed to the idea of full-time clinical professorships, but elicited the information that little was being done in America for post-graduates, and that the best post-graduate school in the States was the Mayo Clinic. In Philadelphia efforts are being made to enable practitioners to get away for six months or a year in order to take up clinical assistantships. There is in this city a special hospital of 250 beds called the Polyclinic Hospital, which is reserved for post-graduate study. America it seems is considering further provision for her own post-graduates, a problem widely different from that which confronts us. The American undergraduate in medicine does not receive a prolonged clinical training in touch with patients, but is instructed largely by classes, both clinical and laboratory. After obtaining his degree the American post-graduate still needs the clinical experience which our students get while acting as clerks and dressers. Mr. Webb-Johnson's letter is crammed with entertaining things. At the Johns Hopkins Hospital he found convincing evidence of the great advantages of having special departments properly equipped in a general hospital. In a description of the operations of one well-known surgeon, "who now removes for hyperthyroidism the bulk of both lobes of the thyroid," it is stated that in spite of the many vessels to be ligatured under this procedure the operation takes 10–15 minutes only. Being ambidextrous, this surgeon uses a needle at both ends of a suture and stitches with both hands at the same time. Mr. Webb-Johnson saw another surgeon expose the third ventricle and foramen of Monro under local anæsthesia without shock or obvious sign of distress. At a famous clinic elaborate precautions are taken against leaving a sponge inside the abdomen; black tails are fastened to the numbered gauze pads by metal rings which can be identified by X ray examination. At this clinic a report on sections by the freezing method reaches the operating surgeon within two minutes. In regard to the keeping of records there is better stenographic assistance provided for American surgeons, who are therefore in a better position to follow up results; this, Mr. Webb-Johnson drily remarks, is more important than recording the proceedings of committees. In Chicago the American College of Surgeons issues a daily bulletin as a guide to all the operative work in the city, and has a department—open also to foreigners—"which will dive into the literature of any subject in medicine or surgery and for a reasonable fee supply a complete bibliography, with abstracts if necessary." The reprint contains photographs of Harvard Medical School, Boston, of the Medical Building of McGill University, Montreal, of the Rockefeller Institute for Medical Research, New York, of St. Mary's Hospital and the Mayo Clinic, Rochester, together with charts, schedules, and history sheets used in the various institutions described. British surgeons will find it worthy of study.

PROPHYLACTIC INJECTION OF NORMAL SERUM AGAINST MEASLES.

EIGHTEEN months ago attention was called[1] to the work of Dr. R. Degkwitz, of Munich, who produced an immunity against measles by injections of serum obtained from patients convalescent from the disease, and our Berlin Correspondent has recently brought our account of this work up to date.[2] Dr. Gustav Salomon,[3] in combating a severe epidemic of measles in the Waisenhaus and Kinderasyl in Berlin, found that the supply of convalescent serum was insufficient to fill his demand, and as the epidemic was a particularly severe one, and every child exposed to infection contracted it, he experimented with injections (10–15 c.cm.) of serum obtained from adults who had had measles in their infancy. He had the opportunity of dividing his cases (all of whom had been exposed to infection) into three groups—namely, 60 children untreated, 62 treated with M.R.S. (Masernrekonvaleszenten-serum), and 72 treated with adult serum. Of the 60 untreated cases all (100 per cent.) became infected and 58 per cent. died; of the M.R.S. children more than half (59·7 per cent.) were protected, while 16 per cent. died; and of the adult serum cases 52·6 per cent. remained immune and 13·8 per cent. died. Out of the 44 deaths, 34 were consequent on broncho-pneumonia, and 10 died while the rash was out. Of the cases which recovered 13 developed broncho-pneumonia. This complication therefore attacked in all 47 cases, 28 of the untreated, 13 of the M.R.S., and 6 of the adult serum cases. The course of the disease, when it occurred in those who had received prophylactic injections, appeared in most cases to be much milder, abated more rapidly, and showed a longer incubation period than the untreated cases. The M.R.S. used in this series was obtained from infants under one year, and was probably not so rich in antibodies as that used by Degkwitz, which was obtained from older children. This fact may account for the lower percentage of good results as compared with his. The prophylactic injection of adult serum appeared to give approximately a similar protection against measles with regard to the incidence, mortality, course of the disease, and complications as the M.R.S. used in this series.

THE BRITISH JOURNAL OF EXPERIMENTAL BIOLOGY.

THE development of most of the sciences to which medicine is ancillary appears now to have reached a stage in which they can no longer be served, in the opinion of those best qualified to judge, by adhering to descriptive methods. While the special journals recognise this tendency and devote an increasing number of pages to experimental work, some delay in publication has become inevitable owing to the large number of men attracted to this side of the subjects, and the result has been the genesis of journals devoted exclusively to the publication of experimental work. Of these the *Journal of Experimental Physiology* is perhaps the oldest in this country, having reached its thirteenth volume. The *British Journal of Experimental Pathology* was founded in February, 1920, and the first number of the *British Journal of Experimental Biology* is now in our hands. The managing editor,

[1] THE LANCET, 1922, i., 591.
[2] THE LANCET, Sept. 1st, p. 476.
[3] Deut. med. Wochens., August 31st, 1923.

Dr. F. A. E. Crew, of the Animal Breeding Research Department of Edinburgh University, assisted by a strong editorial board, will consider original articles on experimental embryology, genetics, animal behaviour, the comparative physiology of the lower organisms, and the results of cytological, morphological, and histological investigations which bear directly on matters of current interest to the experimental biologist. Authors are requested to minimise space devoted to historical introductions and theoretical discussions since authoritative reviews of recent progress in various fields of inquiry will be published from time to time. In the first number a critical summary of Tissue Culture, by H. M. Carleton, gives no less than 55 valuable references, though only "the more important papers have been mentioned," and the author deplores the lack of adequate bibliographical references in many of the articles quoted. It is obvious from his conclusions that many of the fundamental discoveries in this work are due to an English observer. The localisation of the factors restraining, inhibiting, or stimulating the growth of tissues can be approached experimentally through the technique of tissue culture, and such research is in direct contact with the problems of causal embryology and with the cancer problem. The original articles in this issue include Studies on Internal Secretion: II., Endocrine Activity in Fœtal and Embryonic Life, by Lancelot T. Hogben and F. A. E. Crew; Studies on the Comparative Physiology of Digestion, (1) the Mechanism of Feeding, Digestion, and Assimilation in the Lamellibranch Mya, by C. M. Yonge; Parthenogenesis in the Mollusc *Paludestrina jenkinsi* (Part I.), by G. C. Robson; Histological Studies on the Domestic Fowl, (1) A Microscopic Study of Sex-Reversal and Hermaphroditism, by Honor B. Fell. The *Journal* will be published quarterly by Messrs. Oliver and Boyd, Edinburgh, the annual subscription being 40*s*., and we wish it a successful career.

SIR THOMAS BROWNE'S SKULL.[1]

It will be remembered that a peculiar controversy between the Board of the Norfolk and Norwich Hospital, and the vicar and churchwardens of St. Peter Mancroft Church, Norwich, reached a satisfactory conclusion some two years ago. The circumstances were that Sir Thomas Browne, the author of the Religio Medici, who died in 1682, was buried in St. Peter Mancroft, but his skull was stolen from the grave some 160 years later and found its way to the museum of the Norfolk and Norwich Hospital. The vicar and churchwardens of that splendid church, St. Peter Mancroft, were assiduous in attempting to have the skull restored to its original resting place, while the hospital authorities, with a mediæval regard for the relic of a scientific saint, were unwilling to part with the skull. In February, 1922, however, the skull was finally restored to the church, but careful measurements, drawings, and tracings of it were made at the Royal College of Surgeons, so that a memorial might remain of that which is now for ever hidden. There has now been published a monograph on Sir Thomas Browne, dealing especially with the skull in relation to its identity and its verification by portraits written by Miss Tildesley, with an introductory note by Sir Arthur Keith and a report on the endocranial casts by Prof. Elliot Smith. The monograph is a thoroughly sound piece of work. Sir Arthur Keith, who had intended to write it himself, was forced by illness to hand over the task to Miss Tildesley, who has carried it through with enthusiasm and skill—in the words of Sir Arthur Keith, "she has exemplified the best kind of scholarship—one which illustrates the right application of laboratory methods to historical inquiry and to anatomical pursuits." The monograph is profusely illustrated, containing reproductions of the three famous Norfolk portraits, of the portraits at the Royal College of Physicians, London, and at the Bodleian Museum, and beautiful photographs of the skull and the endocranial casts. The scheme for putting on permanent record the physical aspect of the author of the Religio Medici is thoroughly justified. Sir Thomas Browne has won an individual position as author and philosopher, and this monograph should find its way to the shelves of all representative collections. The book has been published by subscription, and we understand that there are still a certain number of copies available to purchasers, who should apply to the secretary of the Biometric Laboratory, University College, London, W.C. The original price of one guinea is being charged for the remaining copies.

SCIENTIFIC EXHIBITS AT THE BRITISH ASSOCIATION MEETING.

Our Liverpool correspondent writes: The British Association meeting this year has an added attraction for the medical profession in its large collection of scientific exhibits. These range from meteorology to practical dyeing, and from preparations illustrating the histology of coal to examples of ultra-modern devices in wireless telephony. Of more direct interest, however, to the medical man are the exhibits of the chemical manufacturers and the scientific apparatus of many kinds for both clinical and experimental work. It is especially noticeable what advances have been made in the production of heat-resisting glass and silicaceous ware. Prices are still high, but are beginning to become more reasonable. It is now possible to buy a good practical Leitz microscope for £18, an oil-immersion lens being £5 extra. A simpler but still useful student's instrument with English lenses can be had for between £9 and £10. Much attention has been paid to the teaching of microscopic work to the student, and some of the apparatus shown would appear to make diagrams—and even lantern slides from actual photographs—things of the past. Two small attachments are exhibited, which enable the teacher to demonstrate a slide directly to the student. One of these is a branched eye-piece, which allows two persons comfortably to examine the same slide at the same time. A movable pointer is an added convenience. Even more practical, and at the same time less costly, is a mirror arrangement which reflects an enlarged view of the field under observation on a sheet of white paper laid near the base of the microscope. Both exhibits can be attached in a moment to any microscope. To the surgeon the instruments produced in stainless steel, though their manufacture is still in its infancy, open up attractive prospects of lessened labour and less frequent necessity for replating, repairs, and renewals. The physician will find the advance of diagnostic methods amply provided for by new instruments of great delicacy and precision, amongst which may be instanced an apparatus for rapidly estimating the reaction of small quantities of body fluids in terms of the hydrogen-ion concentration. There are also to be seen improved and simplified forms of instruments that have already stood the test of time, such as Mackenzie's polygraph. There is a room devoted to the most modern X ray plant that makes its appeal to the clinical worker, as also to the advanced physicist. The visitor comes away with an increased realisation of the part played by the physicist and the chemist in elucidating industrial problems, and an altogether new conception of the rôle of the microscopist in industrial research.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE.

A special post-graduate course, open to all medical practitioners without fee, will be held in the Clinical Theatre of the Unit, St. Mary's Hospital, on Saturday, Sept. 29th, Sunday, Sept. 30th, and Monday, Oct. 1st. On the first day Mr. D. C. L. Fitzwilliams will discuss Early Diagnosis of Carcinoma of the Breast, at

---

[1] Sir Thomas Browne: His Skull Portraits and Ancestry. By Miriam L. Tildesley, Research Worker, Royal College of Surgeons' Museum. With 34 plates, frontispiece, and folding pedigree. Reprinted from Biometrika, vol. xv., and issued to subscribers only.

10 A.M. At 11 A.M. Mr. T. G. Stevens will speak on Prolapse, followed by Mr. S. Maynard Smith on Chronic Pain in the Right Side of the Abdomen. In the afternoon, from 2 to 3, Sir William Willcox will discuss Chronic Rheumatic Toxæmia, and from 3 to 4 Dr. Reginald Miller will give a Demonstration of Cases of Cœliac Disease. On Sunday, Sept. 30th, at 10.30 A.M., Dr. C. M. Wilson will deal with (1) The Investigation of Dyspepsia, (2) The Treatment of Diabetes. On Oct. 1st, at 11 A.M., Mr. Aleck Bourne will give a lecture on Anticipation of Mechanical Difficulties in Labour, illustrated by lantern slides. At noon Dr. Wilfred Harris will discuss Encephalitis Lethargica. In the afternoon, at 2 o'clock, Dr. Graham Little will give a lecture on the Diagnosis of Some Common Diseases of the Skin, illustrated by cases, and at 3 P.M. Prof. Frederick Langmead will deal with Some Functional Disorders in Young Children. It will be remembered that a corresponding week-end course initiated last year was well attended; it may be anticipated that this year's course will be equally successful.

ATOMIC PHYSICS.

PHYSICS has always taken a prominent position in the work of the British Association, a fact which is emphasised this year with Sir Ernest Rutherford, Cavendish Professor of Physics, in the presidential chair. There is much for discussion among physicists at the present day, and Sir Ernest Rutherford was happy in the use of such a term as the "Renaissance in Physics" to describe the extraordinary development in atomic physics during the last 25 years. We have to remember that 50 years ago the generally accepted idea of the atom was that of an indivisible unit which could for most purposes be looked upon as a hard elastic sphere. It had to be elastic because it was known to vibrate, and it was just in this respect, with the advances which were then being made in spectroscopy, that the inadequacy of the concept was most acutely felt, for how could such simple elastic spheres be thrown into the hundreds of different states of vibration which their line-spectra necessitated? The discovery of radio-activity upset completely this conception of the atom, and it is probably not overstating the case if we say that the discovery and isolation of the electron, the ultimate unit (at the present date) of negative electricity, by Sir Joseph Thomson has more than any other single discovery led to this overthrow of the older view. And so it comes about that the researches in atomic physics at the present day are largely centred not on the configuration of molecules but on the internal structure of the atom, and it is by a wonderful combination of intuitively directed experiment by Sir Ernest Rutherford himself, combined with the mathematical analysis of Prof. Neils Bohr, that atomic models are being fashioned which will satisfy the various criteria which natural phenomena provide. This trend of modern physics has, among other things, pointed to the relatively enormous amount of energy which is contained in atoms, and speculation upon its availability has not been restricted to the strictly scientific circle. Experiment has shown that by the use of the swiftly flying alpha particles of radium it is possible to penetrate into the interior of other atoms, to cause their disruption, and in this way release more energy than was in the original projectile. There has thus been a gain of available energy, and if such processes could be multiplied in the scale of some millionfold they might take on an economic aspect, although when experiments are undertaken for big scale operations it is frequently found that some compensatory restraining mechanism crops up. It may be so in this case. There can, however, be little doubt that atomic studies are destined to have far-reaching effects on science as a whole; we are left wondering how many years must pass before a future president will discourse to us on the constitution of the "ultimate" particles of to-day, the electrons and protons which form the bricks of the atoms whose inner structure is the revelation of the present century.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XXXVII.

TREATMENT OF CHRONIC ARTHRITIS.

THE crippling forms of arthritis are among the major causes of ill-health, and through their interference with working capacity account for an enormous economic loss. Three main groups can be differentiated—rheumatoid, osteo- and peri-arthritis. Whilst typical examples of each present distinct clinical and pathological pictures, there are cases difficult to classify and others in which more than one type is seen in the same patient. From the point of view of treatment they can be considered together, points of difference being mentioned as they arise. In all, the joint lesions are local, and often late, manifestations of a general disorder. In rheumatoid arthritis, cramps, tingling and numbness of the extremities, "dead fingers," slight signs of hyperthyroidism, and vasomotor instability may precede the arthritis by years. The subjects of peri-arthritis have usually had fleeting attacks of fibrositis elsewhere before the disease settled in the joints. With osteo-arthritis, villous synovitis of the knees or hips or a dry crackling without joint enlargement may precede the formation of osteophytes, and the appearance of Heberden's nodes on the fingers should suggest the possibility of later and more severe lesions elsewhere. Much crippling and suffering could be prevented if these early symptoms were regarded more seriously and search for the underlying infection were made before the establishment of permanent organic changes.

Treatment of the Infection.

Much emphasis has been placed upon the connexion of focal infections with arthritis. In true rheumatoid arthritis these seem to play but a small part, and infection should be sought in connexion with some mucous surface from which widespread absorption can take place. Many patients show defective ferment action, hypochlorhydria, stasis, and an abnormal growth of intestinal streptococci. The "chronic abdominal" type of patient is well represented in rheumatoid arthritis. The urine may give evidence of alimentary absorption in the shape of streptococci, *B. coli*, and oxalate crystals, and a chronic pyelitis may be present. Chronic bronchitis and uterine infections are less common forerunners, but in some patients all mucous surfaces are unhealthy, and suggest lack of resistance to invasion by the normal bacterial inhabitants. Subinfection leads to hyperthyroidism and lowered sugar tolerance, and these in turn aid further infection. In fibro-arthritis, osteo-arthritis, and gouty arthritis, on the other hand, a careful search for focal infections should be made. The rôle of the teeth has been much exaggerated, and one must protest against indiscriminate and wholesale extraction of the teeth of arthritics. Periapical infections and deep-seated pyorrhœic lesions are important; the open sepsis of simple pyorrhœa is less serious unless there be hypochlorhydria, when the swallowing of septic matter may eventually lead to gross infection of the small intestine. The extraction of teeth requires careful and anxious consideration in consultation with a skilled dentist. In simple pyorrhœa much can be done by scaling, massage of the gums, and strict cleanliness. Removal of septic tonsils may be required; small scarred tonsils are often more dangerous than hypertrophied ones. Enlarged and tender glands beneath the angles of the jaw are good evidence of septic absorption, and the urine may show streptococci of a similar type to those isolated from the mouth or throat or other organisms. The antra and nasal sinuses and the naso-pharynx require careful examination. Gonorrhœa may have opened the path to a secondary streptococcic infection which alone persists and requires treatment. The alimentary tract must be examined for stasis, ulceration, and catarrhal inflammations. Chronic appendicitis or cholecystitis must be considered. Organisms may be grown from the washed mucus from the stools or obtained from the duodenum by a tube. Washing out the small intestine by a saline purge after feeding for a few days with lactose may provide active culture material. A very thorough clinical and bacteriological examination has thus to be made in every case and the results assessed. Only in early cases with one or two accessible foci of infection will removal alone cause improvement; but in later cases we may at least reduce the amount of subinfection.

Vaccine treatment is employed to raise the resistance of the patient to the infection whatever its source. The initial dose should not exceed five millions, and should be very gradually increased, injections being made every five to seven days. That dose which is just below that necessary to produce a reaction should be aimed at. Much vaccine treatment of arthritis is ineffective because it is stopped too soon, with too small a final dose; 1000 to 2000 millions may be reached by careful intensive treatment.

Intravenous Protein Therapy.—The use of intravenous injections of proteins has added a definitely useful agent to our therapeutics, the mechanism of action being somewhat obscure. My own experience has been chiefly with albumoses, typhoid and *B. coli* vaccines, these latter being used purely as a source of protein. With typhoid or *B. coli* vaccine a suitable initial dose would be 30 millions, injections are given every fifth day—usually not more than six in all—the dose being gradually increased according to the effect, up to 200 millions, the dose varying with the patient and the activity of the vaccine. With albumoses I find 0·2 c.cm. of a 5 per cent. solution of Armour's peptone, No. 2, gives a satisfactory response. The injection is followed in a few hours by a rigor and a rise of temperature to 102°F. or thereabouts. During this negative phase there is a focal reaction in the joints with increased pain, followed by defervesence, sweating, and a positive phase in which the joints are less painful and stiff and the patient experiences a sense of well-being. In subacute cases of multiple periarthritis the result may be remarkable; rheumatoid and osteo-arthritic lesions show less improvement, but even here this treatment combined with vaccines yields better results than do other methods. The patient willingly bears unpleasant immediate effects for the sake of the after improvement, and the shortened period of treatment is also of advantage from the hospital standpoint. Intravenous protein therapy should not be used with old and feeble patients or those with myocardial disease.

General Treatment.

Clothing.—Most arthritic patients are overclothed. Layers of heavy woollen clothing keep the skin in an unhealthy, moist, unduly warm condition. Silk or cotton mesh, frequently changed, is preferable.

Climate.—The desirability of a warm, dry climate and of residence on a gravel or sandy soil has been exaggerated; no climate will be found suitable so long as the infective causes remain. Abundant sunshine is of more importance; heliotherapy where tried has given hopeful results.

Diet.—Sugars and soft, starchy foods should be restricted. Rheumatoid patients require a gradual introduction to a generous diet with milk, eggs, meat, abundant fats, and fresh, tender vegetables. Stout osteo-arthritics require a reducing diet, with milder proteins and abundant vegetables. Hot water should be taken before meals, and no fluids with them.

Local Treatment of the Joints.

During the acute phases the joints should be kept at rest *in a proper position.* The majority of advanced cases have their joints fixed in bad positions, brought about in the earlier stages by attempts to get the joints into the position of greatest ease, which is usually that of flexion; as a result adaptive shortening of flexors and stretching of extensors occurs with ankylosis of the joints. Knees and hips should be fixed in extension, if necessary by the use of weights. The elbow should be at right angles and the wrist somewhat hyper-extended. If the patient is unwilling to stay in bed for slow extension by weights he may wear one of the excellent mechanical contrivances which cause traction and take the weight of the body off the joints.

Relief of Pain.—In the early stages some relief of pain will be brought about by the rest and extension. Further relief can be obtained by the application of dry heat, preferably radiant heat. A small lamp with a parabolic reflector, such as that made by the General Electric Company, Moor-street, Birmingham, or the "Thermolite" lamp by Menley and James, is convenient. Hot sand packs provide a homely substitute. After the heat, analgesic applications such as camphor and menthol or methyl salicylate can be applied. The muscles should be gently massaged, but the joints themselves must not be rubbed.

Duration of Rest.—It may be that the best that can be done is to leave the patient with a quiet joint ankylosed in a good position, but more often the question arises—How long should the joint be at rest? No definite rule can be given, but when the temperature is normal and the pain and swelling have subsided changes in position can be made, followed by gentle passive movements. With further improvement active movements are commenced, and the patient must be encouraged to use his joints. Later on we have to deal with stiffness and possibly contractures by stimulating liniments of camphor and turpentine, and by iodine and mercury. This is also the time for hydrotherapy in its various forms and the skilled bathing and massage to be obtained at spas will help to increase mobility. At home the patient may be trained to react favourably to cold baths of graduated temperatures, radiant heat being continued. Ionization may be of use by warming the tissues and stimulating metabolism; diathermy is also of great value.

Orthopædic Treatment.—Patients with partially or completely ankylosed joints may need manipulation under anæsthesia; this requires extreme care and should not be attempted so long as there are signs of activity. There is grave risk of fracturing the bone or rupturing blood-vessels and nerves. When the joint is reduced ankylosis is again allowed in the best position. In a few cases arthroplasty may be possible, especially in cases of ankylosis of the jaw, fixation of the elbow in extension, and ankylosis of several joints in the same limb Complete bony ankylosis gives better results than painful fibrous ankylosis; young adults are the best subjects. Much judgment is required in selecting cases for operation, and prolonged after-treatment is essential.

Drug Treatment.—No drug has a specific action on arthritis; guaiacol carbonate, guaiacum and sulphur, iodides, arsenic, collosol sulphur, and collosol iodine have their advocates. Drug treatment is mainly symptomatic. With rheumatoid arthritis, ac. hydrochlor. dil., min. 20, well diluted after food helps to correct the hypochlorhydria and intestinal infection. Liquid paraffin, collosol kaolin, and dimol may be used for intestinal stasis together with a proper fitting abdominal support. Thyroid is of great value in advanced rheumatoid cases with hypothyroidism and the osteo-arthritis occurring at the climacteric. In acute fibrositis saline diuretics should be used. Hæmatinics can be prescribed for anæmia. Acetosalicylic acid is useful, but is apt to be abused. For catarrhal conditions of throat and nose an atomizer with collosol argentum may be used several times a day and the tonsils swabbed with 10 per cent. argyrol.

The future of these cases is not so hopeless as was once thought. In most cases improvement can be brought about and sometimes the results of treatment are brilliant. No disease requires more patience and perseverance, and the suggestive therapeutics of hope and confidence are more valuable than drugs.

W. H. WYNN, M.D., M.Sc., F.R.C.P.,
Hon. Physician to the General Hospital, Birmingham.

Special Articles.

THE INTERNATIONAL HEALTH OFFICES.

PROPOSALS FOR NEW USEFULNESS.

THE Assembly of the League of Nations, in the intervals of its political preoccupations and anxieties at Geneva, has before it the important proposals of the representative Commission of official public health experts, presided over by Dr. A. Granville, President of the Maritime and Quarantine Board of Egypt, which was appointed in the spring to advise on the lines on which the League's Public Health Organisation should be permanently established.

The Basis of Permanent Organisation.

Hitherto the health work of the League has been conducted by a Provisional Health Committee nominated by the Council and representing ten European and four non-European countries, and by the public health section of the Secretariat of the League, under the directorship of Dr. L. Rajchman. This organisation has carried on its work side by side with the older international public health office in Paris—the Office International d'Hygiène Publique—established by the Convention of Rome, 1907, to which certain countries not members of the League—notably the United States—are parties. The members of the League's Provisional Health Committee are in the majority of cases also the official delegates of their countries to the Paris office, and consequently have been able in large measure to secure that the work of these two international organisations has not unduly overlapped. Moreover, each of the two Presidents, Dr. Madsen (Denmark) and M. Velghe (Belgium), is a member of the other's organisation. All the same, it has become evident that, if two official international health organisations have for the present to be maintained as the result of political and other circumstances, something must be done to coördinate their work, officially and formally, and to establish principles on which the utilisation of the Paris office and the Paris International Committee on the one hand, and the Geneva office and Health Committee on the other, can be naturally and automatically determined. The Third Assembly of the League decided last year that international public health should in future be undertaken as part of the permanent activities of the League, and in working out the details during the present Assembly the League has a great opportunity of getting the desired coördination established by general consent. The report of the Granville Commission proposes that the official Government delegates to the Office International in Paris (who constitute the Standing Committee of that body) should undertake the duty of acting as the General Advisory Body on which the League would rely, and should also accept the duty of nominating the greater part of a Standing Health Committee of the League itself. These proposals keep intact the functions of the Paris office as established under international convention, and, incidentally, have the advantage of basing the medical work of the League on an existing organisation on which the public health services of any country in the world can readily be represented. In effect, they would secure that the regular Committee of the Office International d'Hygiène Publique, which has good work and official experience to its credit, will in future be greatly strengthened through the fact that, subject to the Council of the League of Nations, it will obtain an executive body, able to carry out approved international investigations with the resources of the League behind it—an important consideration when it is remembered that the small budget of the Paris office is limited by its statutes to a sum far smaller than is necessary for effective international work.

A Wealth of Publications.

Consideration of the administrative questions which are now before the Assembly as a result of the report of Dr. Granville's Commission, recalls the magnitude and number of the official international publications which have been appearing for the last two or three years. In addition to the monthly published Bulletins of the Office International d'Hygiène Publique, we now have twice a year the Minutes of that office, which sits in Paris for ten days in May and October, and also the Proceedings of the Provisional Health Committee of the League of Nations, the most recent of which, that of the Sixth Session, has just been issued as a volume of 126 folio pages (League of Nations document C. 424, M. 187), obtainable from Constable and Co. The Health Section of the Secretariat of the League has also issued a number of separate reports on particular conferences and missions, and on epidemic diseases in Eastern Europe. It also publishes a monthly "Epidemiological" Report compiling current returns of notifiable diseases in different parts of the world, which have been gathered together by a sub-department concerned with "Epidemiological Intelligence and Public Health Statistics," directed by Mr. E. Sydenstricker and financed by the Rockefeller Foundation. Study of these various documents provokes the immediate reflection that the coördination desired by the Granville Commission is already badly needed. Few subjects are to be found which are not being treated both by the Office International d'Hygiène Publique and by the Health Committee of the League from their respective points of view, and much cross reference is necessary if the experience of any particular country or the views of any particular delegate are required. It is to be hoped that this is only an incident in a useful evolutionary stage of the development of official international health work. Certainly the publications as a whole leave no doubt of the great progress which has been made at Paris and at Geneva in developing machinery by which the various public health services of different countries are brought together for comparison of data, and for international agreements on matters which require them. Both series of reports, with their wealth of reference, should find a place, together with the monthly Bulletin of the Office International d'Hygiène Publique, in every public health library. It should be understood that the notes below merely illustrate certain sections of the work which is recorded in the most recent of these publications.

International Differences in Cancer Mortality.

This subject was introduced to the Paris office in October, 1922, by Sir George Buchanan, the British delegate, and was made the subject of a preliminary questionnaire, the results of which were reported in May by the same delegate in conjunction with Dr. Major Greenwood, Medical Statistical Officer of the Ministry of Health. The questionnaire was designed as a preliminary inquiry by which the material available for statistical investigation in each country could be ascertained. It appeared that there was unanimity of opinion that cancer is an increasing or, at the least, a non-diminishing cause of mortality in all the civilised nations represented. This opinion was not vitiated by the universally recognised fact that statistical ratios of mortality are liable to various errors of record, some generally applicable and others special to the circumstances of particular countries. The importance of comparative study and analysis of hospital figures is fully recognised, but it is concluded that no country can so far be said to provide records of hospital mortality suitable for the purpose. Notable inter-local differences of mortality have been established in certain countries, in particular a relatively high mortality in the centre part of Sweden as compared with the rest of that country, and in the departments of Emilia and Toscana as compared with the rest of Italy. The constancy of this localisation extends over a considerable period of time, and is not, in the opinion of the reporters, to be accounted for as a matter of record. Recorded cancer mortality shows a very high variation even between the countries in which death certification and registration are most highly developed. This, however, does not carry with it corresponding variations in the rates of mortality at adult ages from all causes. Italy, for example, which has a much lower mortality from cancer than England and Wales, Holland, Norway, and Sweden, has a smaller mean expectation of life at ages 30 and 60 than any of these countries.

Sir George Buchanan and Dr. Greenwood emphasise the value which the replies of the different countries to the questionnaire regarding the nature of the material available for study possess for permanent reference; these replies have now been published in the June and July numbers of the *Bulletin* of the Office International d'Hygiène Publique. It is considered that they will afford a directory and an index indispensable to those who are undertaking international comparison of cancer figures in one or another direction. The reporters suggest one such international comparison as a starting-point, and emphasise the practical value of selecting and concentrating on definite parts of the statistical field. Taking three countries in which registration of causes of death has long been well developed, they present the following contrast between England and Wales, Italy, and Holland :—

Cancer Mortality of Special Sites Expressed as Rates per 10,000.

—	Cancer of the breast (female).			Cancer of the female genital organs.		
	England and Wales.	Italy.	Holland.	England and Wales.	Italy.	Holland.
1911	1·84	0·58	0·98	2·43	1·48	1·17
1912	1·97	0·55	1·19	2·46	1·40	1·27
1913	2·02	0·59	1·08	2·55	1·50	1·40
1914	1·99	0·59	1·10	2·50	1·51	1·31
1915	2·02	—	1·12	2·46	—	1·32
1916	2·11	0·56	1·15	2·47	1·49	1·22
1917	2·13	0·56	1·10	2·56	1·40	1·30
1918	2·07	—	1·12	2·54	—	1·34
1919	2·20	—	1·27	2·55	—	1·44

These are very striking differences, the meaning of which it ought to be possible to ascertain by a carefully planned inquiry, and it is satisfactory to note that the consideration of this report by the Paris office, and subsequent reference of the subject to the League of Nations Health Committee, has led to the appointment by the League of an international committee authorised to coöpt experts and prepare a scheme for the necessary investigations.

Comparative Data in Other Diseases.

A similar collection of information regarding the prevalence of goitre and its treatment, in the hands of Dr. Carrière, the Director of the Swiss Public Health Service, is in progress. In the enteric group the Paris minutes contain instructive contributions from the representatives of some of the Eastern European States such as Roumania and Bulgaria, illustrating the large extent to which wholesale antityphoid vaccination has lately been adopted to combat these diseases among the civil population. The reports contain many references to the present position of epidemic typhus. A notable feature of this disease in Algeria has been that a recent migration of the population from the villages to the towns as a result of drought has led to a very great increase of typhus of the severe type. Figures illustrating the vast extent of recent typhus in Russia are given in the League of Nations volume and in the special epidemiological reports. It is still impossible to obtain any check on these figures, which relate to cases of the disease, by a study of the corresponding deaths, no death returns under causes being available in Russia. There seems to be no doubt, however, that typhus at length after many years shows definite evidence of diminution, while fortunately through a number of circumstances the intensive infection brought into Poland and other countries to the west of Russia, as a consequence of the movements of refugees and repatriated persons from Russia, has virtually stopped. To this fact may be attributed a great reduction in the number of typhus cases in Poland during the past winter, where the weekly number of new cases reported never passed a maximum of 500. In connexion with relapsing fever, which has accompanied these European epidemics, it is interesting to refer to a report to the Office International d'Hygiène Publique by Dr. Gouzien on an outbreak of this disease affecting large tracts of Senegal and French Gambia. It was estimated that since 1919 as many as 80,000 deaths have occurred from this cause. Treatment by injections of "914" were found very effective, but appeared to have the disadvantage of reducing the resistance of the patient to subsequent infection. An account was also given to the Paris office by Dr. Lutrario, the Italian Director-General of Public Health, on an outbreak of ictero-hæmorrhagic spirochætosis of Ronciglione in 1921, causing an epidemic of 800 cases, which terminated by the occurrence of chronic sickness characterised by inguinal buboes.

Malaria and Sleeping Sickness.

The League of Nations Health Committee has recently decided on special investigations in connexion with both these diseases. In May last the British member presented to the Committee a note from Lieut.-Colonel S. P. James, adviser on malaria to the Ministry of Health, in which the great increase of malaria in some of the endemic centres in Europe during and since the war was considered, and a plea was put forward for study of the circumstances responsible for the spread of the disease in the different countries affected. Such an investigation would probably show that some of the preventive methods commonly recommended on tropical experience are not the most effective or most economical for the affected countries in Europe. In many of them only a small amount of money is available for preventive measures; it will not be practicable to employ several systems at the same time, and investigation is needed to determine the one likely to be most effective in the particular instance and concentrate on it. Recent observations in France, Denmark, Holland, and England on the causes of the disappearance of malaria from those countries, and of the failure of the disease to spread in them after the war, may have a very practical bearing on this subject, while thorough inquiry is needed from the point of view of economy into the utilisation of quinine. Following this note the Health Committee appointed a Commission under the direction of Dr. Lutrario with power to coöpt malariologists and undertake local inquiries and other research work. This Commission has the task of collecting and examining information with regard to the epidemiology of malaria and the prophylactic measures adopted, as well as of advising the health administration of different States which may apply to the Commission for assistance.

The inquiry into sleeping sickness in tropical Africa is in the hands of another Commission of the League, consisting of Dr. Andrew Balfour, Dr. Van Campenhout, and Dr. Martin, to which body Dr. Bagshawe, Director of the Tropical Diseases Bureau, London, has now been added. On behalf of this Commission, Dr. Balfour has now presented to the Health Committee a report representing the information available from various sources as to the incidence and distribution of sleeping diseases in the African countries concerned. This report will shortly be published from Geneva. It indicates the need of close practical coöperation between the Egyptian Sudan, Belgian Congo, and French Equatorial Africa on account of the spread of the diseases within those regions and from one country to the other.

International Agreements and Questions of Standardisation.

The minutes of the May meeting of the Office International d'Hygiène Publique show that the proposals for revision of the International Sanitary Convention, 1912, to which so many sessions have been devoted, are now completed and in the hands of the French Government for negotiations with the various powers in order that the final form of the next Convention may be settled by a general International Sanitary Conference. The need for a revised Convention becomes daily more evident, and there will be general satisfaction among those who are responsible for measures of port sanitary administration and quarantine when the date of the Conference is definitely fixed. A minor but collateral question, lately considered by the Health Committee of the League, is that of the international arrangements to prevent carriage of infection that should be made between riparian states which are traversed by large navigable waterways such as the Danube. An annexe to the minutes of the sixth session of the Health Commitee contains a draft model convention for the health control of traffic on waterways prepared with this object by Dr. Chodzko (Poland) and Dr. Lutrario (Italy). Other questions of regularising international practice in the interest of public health and shipping, some of which may require to be included in official international agreements, are those of flags and signals which should be used for various purposes of quarantine, the scope and form of bills of health, and the methods which should be officially considered adequate for the destruction of rats on ships. All these subjects, and in particular the increasing adoption of hydrocyanic acid gas for rat destruction, were fully discussed at the last session of the Office International d'Hygiène Publique, which also received a useful note prepared by Dr. J. A. Mitchell, the chief health officer for the Union of South Africa, on the use of wireless messages in quarantine work.

Another class of work for necessary standardisation must be mentioned. As is well known, the League's Health Committee, through the energy and activity of its President, Dr. Th. Madsen, has already secured some most valuable and practical agreements between bacteriologists and administrators for the unification of certain antitoxic sera and serological tests. The conclusions of the Serological Conferences held at Paris and Geneva on the subject, under the auspices of the League, have already been fully reported, and various joint laboratory investigations which were there decided upon are now being pursued. This year a further step was taken, again on Dr. Madsen's initiative, to obtain an international understanding regarding the units of strength and the methods of testing which should be applied to biological remedies or to drugs which, like digitalis, require to be standardised by biological means. A special conference of physiologists and pharmacologists on these subjects was arranged by the League in Edinburgh in July at the time of the International Physiological Congress. Further publications will be issued from Geneva on these two branches of work, and in both British scientists, acting through the Medical Research Council and otherwise, have fully participated.

Special Activities of the Geneva Health Office.

The provisional health organisation of the League administers the special fund raised for the anti-epidemic measures in Eastern Europe which have been carried out by the League's Epidemic Commissioners. This fund is nearing exhaustion, but owing to the receipt of £5000 through Dr. Nansen, in the early part of this year, it was found possible for the Commissioners to accept the invitation of the Greek authorities and undertake an intensive campaign for the vaccination of the refugees swarming into that country from Asia Minor and Thrace. A very instructive account of this campaign is given in the minutes of the Health Committee in the form of reports submitted by Dr. Rajchman and Dr. Wroczynski. Within two or three months some 700,000 vaccinations were performed against small-pox and 975,000 inoculations of tetravaccine against the enteric group and cholera were given. The whole work appears fully to have merited the special commendation which it recently received from the Council of the League. It may be added that a general investigation of public health problems in the Far East is now being undertaken by Dr. F. Norman White, the Chief Epidemic Commissioner.

The other special funds at the disposal of the League's health organisation—those given by the Rockefeller Foundation—have fortunately not only been continued, but have recently been increased by a special contribution for international statistical services. With the aid of these funds a bureau with a large staff has been formed at Geneva for epidemiological and statistical studies, while considerable progress has been made with the various schemes of "interchange" between the public health and laboratory officers of different countries. The courses of instruction for foreign medical officers of health already held in Belgium, Italy, and Great Britain are now being continued by a course in the United States, and the programme of 1924 covers a second British course, and others in Holland, Switzerland, and the Scandinavian countries. What are termed "specialist" interchanges are also being arranged for tuberculosis and school medical officers; a special course in regard to antimalaria work has already been held in Italy with useful results.

From the above examples it may be concluded that if the present movement for better coördination and consolidation of the work of the two international health offices takes shape, those who are concerned with their future direction will be in no need of a fresh programme. The little group of Government health representatives of different countries, which has laboured so hard at Paris and Geneva to show the practical advantage of international coöperation, has already successfully opened up new and promising lines of progress in practical hygiene, and the coördination should be welcome, perhaps not so much for its opportunities of further increasing the number of medical subjects considered internationally, as for providing means by which the various studies and projects for international arrangements which have now been started can be steadily pursued and brought to satisfactory conclusions.

The Census Figures for 1923.

THE census returns of the Austrian Republic, taken on March 27th of this year, give the total population as 6,526,661. Of these 3,382,568 are females and 3,144,093 are males. The female population has thus reached again the figure of the year 1910, whilst the males still number 141,255 less than at that date. The excess of females is 76 per 1000 males—a higher figure than in 1910, but a lower one than in 1920. Whilst in the rural districts there is an increase in the numbers of both sexes over the 1910 figure, in Vienna and the industrial districts the population has decreased. In three counties only the females have exceeded the figures of 12 years ago. The female population has increased everywhere at a more rapid rate than the male. The ratio of males to females is highest in Wienerneustadt, 1000 : 1003, and lowest in Baden, 1000 : 1268. The birth-rate for the years 1919–21 stands at 17·96, 22·40, and 25·10 per 1000 respectively, while the death-rate figures for the same period are 20·33, 18·97, and 17·06 per 1000. The effects of the war on the census figures are slowly being obliterated. This is also noted in the public elementary schools. Whilst in 1920 the number of children in the first standard of the lowest forms was 20 per cent. less than the previous year, and in 1921 it decreased still further, this year a rise of over 15 per cent. is recorded. These are the children born in 1917, when part of the army had to be sent back home owing to unrest in the front lines; their return home resulted in a rise of the birth-rate. The improved care of the newborn and the young children up to 6 years has caused a marked drop in the mortality figures of these age-periods, so that relatively more children have reached the school age. In the higher forms of the schools the number of children is as yet much lower than in the last five years.

Suppression of Venereal Disease: Police Suggestions.

At the recent international meeting of the police, which took place in this city, reports were made having a bearing on medical subjects. A suggestion was made by the head of the Vienna police to abolish the control of prostitution. He advocates strongly compulsory treatment of all persons, both male and female, found suffering from venereal disease. It is interesting to note that this demand has been brought forward in several instances by medical men at meetings of preventive societies, and that in the Austrian National Assembly's archives there are deposited several Bills dealing with this matter, but which had to be shelved owing to adverse public opinion.

Care of War Victims.

DURING the war and after the German Government, no less than other belligerent Governments, had a heavy burden to bear in the caring for the wounded and providing for the families of the fallen. According to a report recently published, the total casualties in the army and navy amounted to 1,846,293 killed and 4,247,864 wounded. The care of the disabled was formerly entrusted to the local military authorities—the so-called Bezirkscommandos, who in addition had many other duties to fulfil—e.g., the control of the conscripts and the reservists, under the supervision of the War Office. When this military organisation was abolished under the Peace Treaty, the care of the disabled was transferred to the Ministry of Labour and was dealt with by special district offices—Versorgungsämter. Up to the present these offices have settled the claims of 1,537,000 injured and of 1,945,000 dependents. Under the former system the disabled man received his pension and had himself to provide treatment, but the present law provides for the free treatment of disablement due to war service. This enables any one case to be studied as a whole and ensures continuity of treatment. The treatment is, as a rule, carried out by a benefit society; for those who are not members of such societies the Government has appointed medical officers. There are still 70 military hospitals in use throughout the country, and these are given over to the care of the injured. In the German spas the Government have 16 sanatoriums at their disposal, nine of which belong to the Treasury, the others having been taken over temporarily. Private accommodation for invalids is also available in numerous health resorts and spas. In 1922 some 14,500 patients were sent to these institutions. In the tuberculosis sanatoriums 2700 beds are reserved for war victims. In 63 towns and districts there are centres for orthopædic treatment, and necessary appliances, &c., are supplied to patients. A great number of medical officers who formerly belonged to the Army Medical Corps are now attached to the Versorgungsämter.

Accidents Due to Drunkenness.

Dr. Mühsam, chief surgeon to the Moabit Hospital in Berlin, states in the *Vossische Zeitung* that the number of accidents due to drunkenness has greatly increased. He points out that the spread of drunkenness which has grown of late in Germany might well be combated not only by the Government but also by the benefit societies and workmen's insurance clubs, which are called on to pay the costs of treatment, already very high, in such cases of accident.

Height and Weight in Children.

The German Health Office published the results of an inquiry into the height and weight of school-children taken during a period from 1913 to 1922 in the cities of Stuttgart, Leipzic, Munich, Augsburg, Mannheim, Freiburg, Mulhouse (Thüringen), Königsberg, and Spandau. These cities differ much in size and are situated in different parts of Germany. The statistical tables show that boys are taller and heavier than girls of the same age, except at the time of puberty from the eleventh to the fifteenth year. The pupils of the secondary schools are much taller and heavier than the pupils of the elementary schools. The children lost greatly in weight and in size during the war. In Stuttgart the average weight of boys of 10 years fell from 27·9 to 25·7 kg., but this loss had disappeared at the last period of the inquiry which ended in the spring of 1922. It is, however, to be feared that as the supply of food has become again scarce the weight of the children may soon be reduced once more to the war-time level.

Treatment of Tuberculosis.

Prof. Dührssen recently read a paper before the Berlin Medical Society on a new treatment of tuberculosis by inhalations discovered by Prof. Weniger, a German medical man residing in Rio de Janeiro, Brazil. The remedy consists of a mixture of uranium, thorium, manganese, and certain acids which form a new compound, called nitoplasmin. By permeating the capsule of the tubercle bacilli it destroys the toxic and infectious substances, and further it strengthens the immunising substances within the body cells. The daily inhalation of Weniger's compound has no obnoxious or disagreeable effect, the patients, on the contrary, state that they are able to breathe more freely; the sputum first increases, but the discharge is easier and the general state improves, so that they are able to work again. This change was especially notable in graver cases. The condition of the lungs showed an improvement, even at the end of three weeks. Every case was examined before and after the cure by radiographic and bacteriological methods. Dr. Dührssen stated that during his stay in Rio de Janeiro he had seen hundreds of patients who had been cured by Weniger's method within a few months. His own experiences had also been very satisfactory, and he recommended the treatment to the profession.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table gives some of the principal health statistics of the city of Leeds and five county boroughs. If it is justifiable to group the first three as dirty-aired towns and the last three as comparatively clean-aired towns, it is suggestive that the average death-rate of the first group from disease of the respiratory system with influenza is 2·3, while that of the second group is 3·8, and that the difference is greater than the total tuberculosis mortality rate in any of the six towns.

Name of town.	Estimated population (R.G.)	Birth-rate.	Death-rates per 1000 of population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Respiratory with influenza.	Infant mortality		Maternal mort. in childbirth.
							Legit.	Illegit.	
Leeds C.	466,700	19·8	13·9	1·4	1·3	2·9	97	166	3·4
Wigan C.B.	91,750	22·4	14·2	1·2	0·6	4·0	108	93	3·0
Bury	57,400	16·5	14·9	0·9	1·2	4·4	71	274	6·3
East Ham	145,800	21·0	11·0	1·2	1·2	2·7	61	148	1·6
Derby	132,400	20·8	11·3	1·1	1·2	2·2	68	144	4·0
Bournemouth	81,500	13·8	14·0	1·2	1·7	2·0	53	100	5·3

C.=city. C.B.=county borough.

Leeds.

Dr. J. Johnstone Jervis reports that owing to the numerous conversions of premises into flats (55 houses were converted into 260 flats in 1922), Regulations for underground sleeping rooms under Section 17 of the Housing Act of 1909 have been adopted and submitted to the Ministry. The control of common lodging-houses has been transferred from the Watch Committee to the Health Committee. Application will shortly be made to the Ministry to extend the definition of offensive trades to include fried-fish shops and rag and bone dealers. The local Fish Friers' Association approve the former proposal as they are anxious to have the unsuitable premises brought up to the high standard of the majority. Dr. Jervis, in dealing with the smoke nuisance, says the railway companies are among the worst offenders. Lectures for stokers were arranged at the Technical School in November and December, and were well attended. Out of about 7000 observations (one hour each) of chimneys during 1921 and 1922, there were 556 cases where chimneys emitted dense smoke for three minutes. There were no prosecutions in either year.

The Milk Order has met with a poor reception so far in Leeds, licences having been issued to one retailer for "certified" milk and to one for "pasteurised." The two corporation farms have, however, recently been licensed for grade A (tuberculin tested) milk and supply two sanatoriums, the Infants' Hospital, the residential nursery, and the one remaining day nursery (the other three day nurseries having been closed as unnecessary). About 10 per cent. of the milk samples were returned as adulterated. The inspection of cow-sheds shows that the country cows compare very unfavourably with the city cows for cleanliness. Dr. Jervis comments on the culpable negligence shown in protecting meat, bread, fish, fruit, &c., from contamination. Mussels from Lytham and Hoylake are excluded from the Leeds market on account of sewage contamination. There is urgent need for more hospital accommodation for acute bronchitis and pneumonia. Another need is an increase in the ambulance service, for dealing with maternity cases amongst others.

The percentage of persons abandoning treatment at the V.D. clinic before cure is complete reached the low figure of 7·8 in 1922. Dr. Jervis is very dissatisfied with the tuberculosis scheme and does not think the reduction of the tuberculosis death-rate from 1·74 in 1913 to 1·40 in 1922 is a result commensurate with an expenditure of £116,444 during the last ten years. Other people might think the expenditure well worth while if they could feel assured the reduction was due to it. Dr. Jervis goes on to say that if half the money spent on tuberculosis were spent on slum clearance and better housing the result would be much more satisfactory. Well, the Government is now offering Leeds £2500 a year for 20 years (total £50,000) towards slum clearance, to which Leeds will presumably add a like amount, making a sum in all not far short of half the Leeds tuberculosis expenditure. However, it is futile to talk of scrapping tuberculosis expenditure altogether, and Dr. Jervis recognises this when he says "A proper sanatorium built on up-to-date lines is badly wanted," and welcomes the gift of "The Hollies," a mansion which will accommodate 50 children and "be a valuable addition to the general scheme for the treatment of tuberculosis in the city." At the same time everyone will sympathise with Dr. Jervis's desire that more should be done to strengthen the resistance of contacts and to secure the complete convalescence of children after debilitating illnesses "by the establishment of recuperative centres and preventoria up and down the whole country."

Wigan.

Dr. Henry Whitehead is able to report that the scheme for conversion of privies and pail-closets to the water-carriage system has been begun and that great progress has been made in dealing with insanitary houses. Proper receptacles are needed for house refuse, up-to-date vehicles for its removal, and Dr. Whitehead emphasises the need for watering the streets before sweeping in dry weather. The construction of a public slaughter-house is under consideration. An inspection of the gathering grounds of the Wigan water-supply has revealed sources of pollution. Chlorination has been adopted for two of the three supplies and steps to prevent the pollution are being considered. Two additional maternity and child welfare centres have been established. Advantage is to be taken of the Government-assisted scheme for dealing with unhealthy areas, and two such areas are at present being carefully considered. Dr. Whitehead's school report shows that many things are lacking. There is no arrangement for the treatment of tonsils and adenoids. A residential open-air school and an open-air day school are needed and either a special school or more special classes in order to carry out the statutory requirements for the education of mentally and physically defective children. An additional school clinic is wanted. There is ample work for a whole-time dental surgeon, but the school dentist at present only gives three half-days a week to inspection and treatment. A recently completed inspection has shown that the sanitary condition of the schools leaves much to be desired.

Bury.

Dr. G. Granville Buckley shows that the phthisis and infant mortality rates were the lowest ever recorded. He issues a warning as to the neglect of vaccination. At present only one child out of every five born is vaccinated. Bury is setting an example to the mill towns in smoke abatement. There were two prosecutions, one of which resulted in a £5 penalty, the other being dismissed. In over 4 per cent. of the chimneys observed, black smoke was emitted in excess of the limit of 2 minutes in 30 laid down by the Bury Council. One observation showed $28\frac{1}{2}$ minutes black smoke and $1\frac{1}{2}$ of moderate smoke in 30 minutes!

East Ham.

Dr. W. Benton reports that an up-to-date steam disinfecting station is needed. An agreement has been made with West Ham Corporation for dealing with small-pox cases.

Judging from Dr. Benton's report as school medical officer, the East Ham Education Committee do not take their duties very seriously. Only children whose acuteness of vision is $\frac{6}{18}$ or less are offered the chance of treatment at the school ophthalmic clinic.

The two rooms occupied by the dental clinic were built as store-rooms and are totally unfit for the practice of dentistry. The system of charging has interfered with the attendance and retarded the work. The appointment of at least one more dental surgeon is urged. The dental needs of children over 10 years cannot be systematically dealt with. The school dentist, Mr. Cyril S. Neame, who also treats cases sent by the maternity and child welfare centres, comments on the wonderful improvement in the health of the mothers treated (although to his regret he has not the facilities to provide dentures), and mentions that it is no uncommon thing for him to treat babies of 19 months who have septic mouths and require three or four extractions. The results of past years' work are becoming evident in the lessened amount of oral sepsis among the scholars.

Dr. Benton emphasises the need from the preventive point of view for proper provision being made for the large number of delicate and pre-tuberculous children in day and residential open-air schools and schools of recovery. From the lack of a cleansing and disinfecting centre for the treatment of uncleanliness, scabies, and other skin diseases the education of many children is interfered with. During 1922, 12,145 school sessions were lost by children suffering from such conditions, as compared with 10,113 in 1921.

There are no special centres available for the education of physically or mentally defective children unable to attend ordinary public elementary schools. A remedial clinic, with massage, &c., is needed for cases of infantile paralysis, spinal curvature, &c. Dr. Benton points out that the scheme in operation for securing payment from parents for the cost of treatment has resulted in a setback to the work of following up, and that the school nurses are likely to become unwelcome officials rather than friendly advisers. The primary consideration, he urges, should be to secure treatment, and the financial question should form no part of the duties of members of the school medical service.

Derby.

Dr. Albert E. Brindley tells us that 1922 was a "measles" year. There were 2618 cases notified, with only 12 deaths, and this lower mortality as compared with past measles years he claims as being in no small measure due to the educational efforts of the health staff. The figures for 1922 show that the death-rate among hand-fed babies was nearly four times that of those naturally fed. Dr. Marion Knowles, maternity and child welfare medical officer, says the work of the dental clinic grows slowly, but that the old idea that nothing can be done for the teeth during pregnancy dies hard. She is anxious that the clinic should provide dentures for the mothers in necessitous cases. Dr. W. H. Wray, tuberculosis officer, states that an endeavour is being made to limit admissions to the sanatorium to early cases and to increase the length of stay. The average stay per patient was increased from 90 days in 1920 to 196 days in 1922. Nine shelters are on loan for continuing sanatorium treatment at home, and Dr. Wray thinks this method might be usefully extended. Two cases of anthrax of the localised type occurred during the year. In each case the patient worked at a tannery and was treated successfully by operation at the Derbyshire Royal Infirmary. The source of origin was said to be imported goat skins.

Bournemouth.

Dr. A. D. Edwards thinks the Registrar-General has considerably under-estimated the population. He therefore gives some of the principal statistics obtained on his own estimate of 93,770 and on the Registrar-General's of 81,500 side by side. For purposes of comparison between the various towns the only equitable method is, obviously, to accept the Registrar-General's estimates. Perhaps, too, it is better for a health resort to be stimulated by an over-estimated death-rate than lulled to sleep by an under-estimated one. The Corporation housing scheme consists of 164 houses, 162 built by contract and two presented to the town by the Builders' Guild. Each house contains at least three bedrooms, a parlour, and bathroom. The weekly rents, inclusive, except for water-rate, are as follows :—

Ministry type.				Number.
B.	3-bedroomed	semi-detached ..	12s. 6d.	88
B4.	4- ,,	,, ,, ..	14s. 0d.	6
B.	3- ,,	in block of 4 ..	12s. 6d.	60
B4.	4- ,,	detached.. ..	15s. 6d.	4
B.	3- ,,	,, ...	14s. 0d.	6

The applicants were divided into Bournemouth ex-Service men married with families, married without families, and single ; and Bournemouth non-ex-Service men and non-Bournemouth ex-Service-men similarly subdivided. Nearly all the tenancies were allotted to Bournemouth ex-Service men with families. Four of the four-bedroomed houses have been adapted, so that each may accommodate two families, each co-tenant being responsible to the Corporation for half of the rent. On written application the committee may grant permission to sub-let, provided the sub-tenancy includes a sitting-room, a bedroom with fireplace, and joint use of scullery fittings, bathroom, and water-closet. The sub-tenant is liable for not more than half of the rent and water-rate, which he pays to the tenant. On Dec. 31st, 1922, there were 37 sub-tenancies recorded in the register. The committee may grant permission to keep poultry. The number is limited to eight fowls, and the height of the hen-house to 5 ft. On Dec. 31st, 1922, there were 75 poultry runs. The erection of 18 sheds for cycles, &c., has been permitted up to the present.

The public analyst, Mr. R. A. Cripps, reports that four of 21 samples of cream illegally contained a boron preservative, and that samples of sponge cake contained boric acid up to 31½ gr. per lb. The boric acid in the latter case is used to preserve the liquid eggs used for making the sponge cake. Of 21 samples of green peas 16 contained copper, in four instances undeclared. It is customary in Bournemouth not to take proceedings if the presence of copper is declared on the label and the quantity does not exceed 2·0 gr. of sulphate of copper to the lb. of peas. Penalties of £2 and £1 11*s.* 6*d.* costs were obtained in respect of five samples, the highest amount of copper sulphate present being 4·1 gr. to the lb. In a sample of lime-juice cordial about half the acidity was due to adulteration with phosphoric acid. Mr. Cripps comments on a successful defence of this practice in London, when it was claimed to be an improvement. He is still of opinion that this practice is a gross fraud, and suggests that if it is permissible to replace the natural constituents of a foodstuff by cheaper substitutes under the specious plea of "improving," the manufacturer might advertise the "improvement" on the label and there would then be no prejudice to the purchaser, especially if the price charged corresponded with the reduced cost to the maker.

SCHOOL MEDICAL SERVICE.

Derbyshire.

DURING the year 26,744 children were medically examined, 26,389 of these coming under the routine age-groups. Of the latter 6702 were referred for treatment, and during the year 2505 children received treatment for eye trouble, 3605 for ear disease. Operations for diseased tonsils and adenoids were performed upon 1155 children, and these are excluded from school for two weeks after operation ; 151 cases of ringworm were treated by means of X rays.

Dr. Sidney Barwise demonstrates that the boys and girls in Derbyshire are taller and heavier than the average of the same class in England and Wales, but in the later ages the advantage is not maintained. Examination of the secondary school-children reveals the fact that postural deformities, with the exception of flat-foot, are much less common in boys than in girls. Of 816 boys examined, 54 had more or less flat-foot ; 2 per cent. had colour blindness. Of 1803 girls examined in the secondary schools 270 had enlarged or septic tonsils and adenoids. Goitre was present in 194. In the more marked cases it was fairly easy to persuade the parents to have the condition treated, but in far too many of the milder cases it is still regarded as just Derbyshire neck—something that runs in the family. Tables are given showing the personal equation of the doctor in discovering and recording defects, the percentage of children referred for all conditions varying in different doctors' districts from 33·6 to 11·5 per cent. During the year 861 children were excluded from school : 105 because they were verminous, 755 for medical reasons, 287 of these being on account of tuberculosis. There were 17 permanent exclusions from school, 7 of them being on account of mental condition, 2 for epilepsy, and 2 for defective vision.

Dr. Mary Gallagher gives the results of 983 cases of enlarged tonsils and adenoids upon which she had operated. In one-half of these cases the condition had caused secondary complications, such as suppurating middle-ear disease or chronic catarrh of the middle ear with deafness, chronic inflammation, and discharge from the nose. In a considerable number of cases operation had to be deferred owing to treatment for anæmia, septic teeth, &c., having to be carried out. In one case the child had to be treated for six months before she was fit for operation ; considerable pains have been taken to follow up these cases. Of the 983 cases operated on, 890, or 90 per cent., were discharged cured and 83 improved. In 10 cases there was no improvement. In several cases operations were performed on children who had already been operated on with the guillotine—that is, a piece of the tonsil had been sliced off, and after a short time the symptoms had unfortunately recurred. The cardiac condition of 30 children was such that the operation was performed without an anæsthetic.

The school dentist submits an interesting report. He finds that out of the number of children inspected 80 per cent. were referred for treatment and 20 per cent. actually treated. He insists that any propaganda for the prevention of caries in children must depend on the teachers. Dental extractions amounting to 19,936 and 13,526 dental fillings were accomplished. This is a considerable increase on the figures for previous years; more than twice the number for 1920 and three times that for 1918. The extra work was accomplished at a comparatively small increase of expenditure by the use of dental dressers. It would be interesting to compare the cost per head for 1922 and 1918. The employment of dressers for the unskilled work is found to reduce working costs considerably, with no loss of efficiency. Sanction has been granted by the Board of Education for the continuance of this experimental scheme for a further two years, by which time, it is hoped, it will have thoroughly vindicated itself.

Derbyshire Education Committee are certainly to be congratulated on the consistent way in which they have tackled the problem of treatment of defects found among the rising generation. As long ago as 1909 they started a scheme for dental treatment. They were also pioneers in the introduction of X ray treatment for ringworm, which has made such a difference in school attendance statistics all over the country. They have established a specialist service conspicuous by its conscientious work. The medical and nursing staff here have had to be reduced in the interests of economy, but it is to be hoped that the economy campaign will not deal too ruthlessly with a scheme of treatment built up with so much care and foresight.

STORY OF THE SMALL-POX EPIDEMIC IN GLOUCESTER.

AT a special meeting of the Health Committee of the City of Gloucester held on Sept. 7th, a report on the circumstances of the recent small-pox epidemic in that city was read. This report was approved and adopted by the committee with only one dissentient. The following extracts from the report outline the main facts attendant on the outbreak of the disease and on the administration of the powers of the local authority in dealing with it. The extracts embody suggestions for the better working of the Public Health Services, arising from conclusions arrived at by the acting medical officers of health and approved by the Health Committee. The report states:—

Prior to the month of June, in March and April, only six cases of small-pox in the city had been *notified, registered,* and *reported as such to the Ministry of Health.* These cases were all sent to the small-pox hospital at Longford and were in due course discharged; and at a meeting of the council on May 30th the chairman of the Health Committee (Councillor Wood), relying on the report of the medical officer of health, stated that the city was then quite free from small-pox.

Cases Diagnosed as Chicken-pox.

On June 1st Dr. J. R. Hutchinson, a medical officer of the Ministry of Health, came to Gloucester and late in the evening had a conference with the Mayor (Councillor J. O. Roberts), the chairman of the Health Committee, Alderman Dr. Knight, and the medical officer of health (Dr. Bibby), and stated that he had been sent to Gloucester by the Ministry to inquire as to the existence of small-pox in the city, having regard to the fact that although cases were notified in surrounding districts, some of which were believed to have become infected from Gloucester, no cases were being notified from Gloucester, that he had visited a number of cases which had been notified as chicken-pox and found them to be small-pox, and that he had found other cases of small-pox which had not been notified in any way. As it appeared that the medical officer of health questioned Dr. Hutchinson's diagnosis, it was agreed that Dr. Hutchinson should arrange for an expert to come to Gloucester and report upon some of the cases. In the evening of the following day (June 2nd) Dr. Hutchinson returned to Gloucester with Dr. A. F. Cameron (medical superintendent of the rivers hospitals and ambulance services of the Metropolitan Asylums Board) and had a conference with the Mayor, the chairman of the Health Committee, and the town clerk, when Dr. Hutchinson reported that since their arrival they had seen the medical officer of health and examined about 16 patients, Dr. Cameron agreeing with Dr. Hutchinson that, with the exception of one case of chicken-pox, all the patients examined were suffering from small-pox. Dr. Hutchinson intimated that the course to be adopted was fully explained in Memorandum 71a issued by the Ministry in November last (which was laid before the Health Committee when issued, and again in March last), but he also made a number of suggestions for the guidance of the committee.

On June 3rd Dr. Cameron and Dr. Hutchinson had a further interview with the Mayor, when Dr. Cameron stated that he had examined 15 more patients, making 31 in all, and that, with one exception, they were all suffering from small-pox.

A special subcommittee was formed to consider any question arising in connexion with the outbreak of small-pox with power to deal with any matters of urgency.

Appointment of Dr. W. H. Davison.

At a meeting on June 11th of the special subcommittee formed to deal with the outbreak the chairman reported that he had been to Birmingham and, through the kindness of the corporation of Birmingham, had arranged for Dr. W. H. Davison (assistant medical officer of health) to come to Gloucester for a month to assist the medical officer of health in dealing with the outbreak of small-pox. It was then resolved—

> "That Dr. W. H. Davison be requested to deal with all notifications of small-pox and chicken-pox, arrange as to the course to be adopted for investigating, dealing with and following up such cases, and generally dealing with the epidemic; and that he be given plenary powers with regard to such matters, including authority to give directions to the staff of the health department and visit patients in hospital."

At a meeting of the Health Committee on June 15th it was temporarily arranged (subject to the sanction of the Minister of Health) for Dr. Davison to perform any of the duties of a medical officer of health, in connexion with the existing outbreaks of small-pox and chicken-pox in the city and measures for preventing the spread of such diseases; and he was accordingly appointed to perform all or any of such duties with all the powers of a duly appointed medical officer of health. The committee also passed a resolution recommending the council to delegate to them and to the special subcommittee, during the present outbreaks of small-pox and chicken-pox or until further order, authority to exercise any of the powers of the local authority or corporation under the Public Health Acts, 1875 to 1907, the Infectious Disease (Prevention) Act, 1890, and the Gloucester Corporation Acts, 1894 and 1911, with respect to those diseases and measures for preventing the spread thereof; and such recommendation was duly approved and adopted by the council. The hospital at Brockworth was opened for the reception of patients on June 15th.

Difficulties of Public Health Administration.

At a special meeting of the council on June 20th Dr. Davison read a report dealing with the epidemic in which he stated that as the outbreak had been allowed to go unchecked for such a long time, great difficulty was experienced in getting patients to agree to removal to hospital. There were certain influences at work endeavouring to foster this resistance and throw sand on the administrative machinery designed to protect the community. An emergency meeting of the Health Committee was held on June 23rd. Dr. Davison stated that the present conditions made it impossible for him to continue to take administrative charge of the epidemic, and referring to the fact that he had pointed out that it was a ridiculous position to have in charge of small-pox cases a medical superintendent who did not admit the cases to be small-pox.

Resignation of Dr. J. R. Bibby.

At a special meeting of the Health Committee on June 25th the chairman referred to the fact that at the last meeting it was explained that the subcommittee had suggested to the medical officer of health that, having regard to his views about the epidemic, he should temporarily relinquish all duties in connexion therewith and that he had refused to do so. After hearing the report of members of the committee who had since seen the medical officer of health, it was resolved—

> That it be recommended that, as far as practicable, and until further order, the medical officer of health (Dr. Bibby) be relieved from all duties connected with the diagnosis of cases of small-pox and chicken-pox and the admission to hospital of cases of small-pox and their subsequent treatment and discharge; and also from the superintendence, administration, and visiting of the hospitals at Longford and Brockworth.

At the same meeting Dr. Davison stated that it would be necessary to obtain additional medical assistance, and it was decided to apply to the Metropolitan Asylums Board for two suitable men. This resulted in Dr. R. W. Jameson and Dr. G. R. Painton coming to Gloucester on June 27th, when it was arranged that Dr. Jameson should take charge of the hospital at Brockworth, and that both should assist Dr. Davison generally in dealing with the epidemic. At a meeting of the special subcommittee on June 29th Dr. Davison advised that Dr. Jameson and Dr. Painton should be authorised to exercise the powers of a medical officer of health, and a resolution recommending that course was passed, and in due course approved by the council and the Minister of Health.

Dr. Bibby sent in his resignation as medical officer of health for the City and the Gloucester Division of the Customs Port of Gloucester, which was accepted.

At a meeting of the Health Committee on July 6th Dr. Davison reported that at 9 o'clock that morning there were 230 patients at the Brockworth Hospital. In connexion with the medical assistance which the committee have had in dealing with the epidemic, it should be mentioned that Dr. C. Killick Millard, medical officer of health of Leicester, had intended to take a holiday in Switzerland, but in order to assist Dr. Davison very kindly spent three weeks of his holiday at Gloucester, without any remuneration beyond hotel expenses and railway fares—a service which has been much appreciated.

Incidence and Treatment of Small-pox in the City.

As many cases of small-pox had been wrongly diagnosed as chicken-pox instead of small-pox, and therefore had not been isolated, it was found when Dr. Davison came that there were a number of cases of small-pox in the city and it was necessary to deal with such cases and their contacts. This was done in a very thorough manner, and contacts were kept under surveillance and offered vaccination. The largest number of patients in the hospital at any one time was 254, the total number admitted up to date being 507; but all have now been discharged, except 13, and it is hoped the epidemic is practically over. The admissions for the week ended noon, Sept. 4th, were two, in different houses, both contacts who had developed the disease.

Mild Type of Small-pox.

The epidemic is referred to as "mild" small-pox as some 70 per cent. of the cases have been very mild, 25 per cent. moderately severe, and 5 per cent. severe, with only three deaths, only one of which was caused by uncomplicated small-pox, and this an infant 6 weeks old, small-pox being a contributory factor in another death, and not even a contributory factor in the third death, though the patient had a mild attack. Owing to the mildness of most of the cases, some persons appear to have mistaken them for chicken-pox, but the subcommittee were advised that they were certainly small-pox, and that is not only the opinion of the experts engaged by the council and most of the medical men in the city, but that diagnosis has been confirmed by many medical officers of health and other medical men who have visited the hospital. As showing that the disease is quite distinct from chicken-pox, the subcommittee are informed that it has been found that the one disease is not a protection against the other, and that, while vaccination is a protection against small-pox, a person suffering from the disease cannot be successfully vaccinated.

This mild type of small-pox is stated not to be new. A circular letter was recently issued by the medical officer of health and assistant medical officer of health of Bristol to medical practitioners of that city stating that they had had an opportunity of seeing cases of the present outbreak in the Gloucester Hospital and found that they *resembled in every particular* the mild cases which were being constantly introduced in Bristol in 1903–4, and as constantly stopped from spreading by the loyal coöperation of the medical profession, and pointing out the urgent importance that it should not be mistaken for chicken-pox.

As far as is known to Drs. Painton and Jameson, the Gloucester epidemic appears to be strictly comparable and indeed identical with what has been going on in Yorkshire, Derbyshire, and the Midlands during the last two years, and something of the same kind appears to have been met with in America where, in order to distinguish it from the more virulent type, it is sometimes called alastrim. The consensus of medical opinion and the evidence seem to show that the disease is undoubtedly small-pox and quite distinct from chicken-pox, though the patients have not suffered from some of the more severe symptoms met with during the epidemic of 1896. As showing that a mild case may cause a much more severe one, reference may be made to cases which occurred in one family in June last. A girl, aged 12, had an exceedingly mild attack. She gave it to a brother aged 14, who was one of the worst cases dealt with. It is very important, the report states, that cases of small-pox should be promptly and carefully isolated; but apart from any question of wrong diagnosis, it would appear that, as in 1896, there have been cases of concealment.

History of a Typical Case.

C. N. S. was admitted as a patient at the small-pox hospital on August 30th. From the report of Dr. Painton it appears that on August 25th the patient, who had been at home unwell since the previous Thursday, sent for a doctor, and was seen by Dr. L., who thought he was suffering from influenza. On the following Thursday, August 30th, as the patient had not been to work for a week, his employer requested a doctor to find out why he had not come to work, and as a result Dr. L. again saw C. N. S., and reported at the health office that he was suffering from what he considered to be an attack of small-pox and asked that Dr. Painton should see the case. Drs. Painton and Jameson visited the case the same day and found it to be undoubtedly one of small-pox and the patient was willingly removed to the small-pox hospital. The patient has since been seen by a number of local medical men and also by two experts who all agreed that the patient was suffering from small-pox, one of the experts certifying that "the illness and present condition are typical of the disease," and the other that "the symptoms and features of his illness are quite characteristic."

The prodromal history of the case is described in the following statement made and signed by the patient on Sept. 1st:—

> I was first ill on Thursday morning, feeling dicky, headache, pains in my legs and as if I had an influenza cold coming on. I laid down till dinner-time and then sat about. Feeling a bit better on Friday morning I stayed in house and garden on Friday. On Friday afternoon I felt a lowering pain in my lower back across from one side to the other. On Saturday morning, after the night's rest, I felt a bit better. Later in the day about dinner time I felt I was going to be bad and sent for Dr. C. Dr. L. came. I was in bed when he came. I felt queer. I felt hot over my body, just as if a cold was coming on from Friday morning on till Monday. I ate my dinner on Sunday, but did not enjoy it. On the Thursday the pain in my legs was very bad. I felt better on Monday and went to Court. On the Tuesday morning, when I got up at 8 o'clock, I noticed spots on my arms. The rest of the rash came out on the same day, Tuesday, just as it is to-day. No rash came out on the Wednesday. Dr. H. saw me on Sunday, Monday, and Tuesday, and he called again on Wednesday night to count the spots on my little girl's hand, and he looked at my hands and face again then.

The local authority and those helping them have had to contend with great difficulty and obstruction in dealing with the epidemic, and it is pointed out that the public must realise that unless steps are promptly taken to correctly diagnose doubtful cases and to notify cases which ought to be notified, they will always be liable to epidemics and the trouble and expense resulting therefrom.

The Reporting of Notifications by the M.O.H. to the Ministry of Health.

When a notification is sent in it is to be assumed that the case is one for investigation and the notification should be acted upon unless, as a result of consultation with the medical officer of health, or otherwise, the person making the notification should feel justified in withdrawing or revising it; but if a medical officer of health should not agree as to the correctness of the diagnosis of a case as notified by a medical practitioner, the proper course would appear to be for the medical officer of health to report the notification to the Ministry of Health with his own view of the case in order that any doubt as to the diagnosis may be promptly decided. If that course had been adopted in Gloucester, any question of diagnosis might have been dealt with in January, at which time recent inquiries show that the disease existed, instead of June, all the early cases might have been promptly isolated in the hospital at Longford, and, in all probability, the anxiety and great expense involved in connexion with the hospital at Brockworth and the isolation and treatment of a large number of cases therein might have been avoided, as well as the indirect but far greater loss to traders and others resulting from the adoption of a wrong course and the wide publicity given to the matter in the public press.

The general facts with regard to the epidemic are shortly summarised in this report; but much valuable information is contained in reports made from time to time to the subcommittee by Drs. Davison, Painton, and Jameson, and particularly in the following: (1) Report by Dr. Painton on the epidemic viewed from the administrative point of view; and (2) report by Dr. Jameson on the hospital aspect of the epidemic.[1] While referring to such reports the subcommittee desire to place on record their great appreciation of the very valuable assistance rendered by Drs. Davison, Painton, and Jameson, and of the able manner in which the epidemic was dealt with by them when called in, although it had been allowed to get widely distributed through the city.

---

[1] Copies of the Reports of Drs. Painton and Jameson are being printed with reproductions of the photographs, maps, and charts, and a limited number of copies may be obtained from Messrs. L. A. Smart and Sons, Northgate-street, Gloucester. Price 10*s.* 6*d.*

Questions Raised by the Epidemic.

In conclusion, the report makes the following statements :—

The facts connected with the epidemic raise questions of great importance which seem to require careful investigation, and it would appear desirable that the Ministry of Health should consider the circumstances leading up to and connected with or incident to the epidemic, and also consider the following and other incidental matters :—

1. The adequacy of the provisions of the Infectious Disease (Notification) Act, 1889, and the need for amending the same or amending or more clearly defining the duties of medical officers of health, so as to make sure that cases notified shall be investigated and properly dealt with.

2. The need for adequate facilities for ascertaining whether any inmate of a dwelling-house is suffering from an infectious disease. This appears necessary as the admission of the acting medical officer of health was for a time refused ; and, although there is power of entry for a variety of purposes, there does not appear to be any for a case of this sort.

3. Having regard to the fact that this mild type of small-pox is *very infectious*, though some persons appear uncertain about the diagnosis, it appears necessary for the protection of the country generally that prompt and reliable measures should be taken to find and deal with cases which may occur ; and as prompt isolation of cases is essential for the protection of the country at large, it is submitted that this should be enforced by the Ministry, and that the cost, or a large part of it, should be contributed out of Government funds.

THE DENTAL STUDENT.

A GUIDE TO TEACHING INSTITUTIONS IN DENTISTRY.

THE Students' Number of THE LANCET, which appeared on August 25th, contained information likely to be of use to those who propose to take up dental surgery as their career in life. An account was there given of the functions of the Dental Board, of the conditions for registration as a dental student, and of the examining bodies in dentistry. Of teaching institutions those connected with the several universities were described in some detail, but in addition to these there are a number of institutions which offer facilities to dental students and which are now set out under their localities.

LONDON.

Royal Dental Hospital of London, School of Dental Surgery, Leicester-square.—A school of the University of London, and women are now admitted as students and are eligible for all hospital appointments and school prizes. The school provides the special dental education required by the Royal College of Surgeons for the Licence in Dental Surgery. The general part of the curriculum may be taken at any general hospital. The hospital is open from 9 A.M. to 5 P.M., there being one staff for the morning and another for the afternoon of each day. Pupils are received for the training in dental mechanics recognised by the curriculum. The instructors at the commencement of each session give a course of lectures on Operative Dental Surgery. The five house surgeoncies are held for six months each and are open to all qualified students. The lecturers, in addition to their lectures, give special demonstrations on the Microscopy of Dental Anatomy and Dental Surgery. The lecturer on Dental Mechanics also gives practical demonstrations in the laboratory. There is an Entrance Scholarship in Chemistry and Physics of the value of £50. One Entrance Scholarship in Dental Mechanics and Metallurgy, value £25, open to pupils of the Hospital only. One Entrance Scholarship of £25 in Dental Mechanics, open to pupils of private practitioners. The Saunders Scholarship of £20 and Saunders Prize of £5 awarded to second year students. The Storer Bennett Research Scholarship for Scientific Research in any branch of Dental Surgery, value £50, is awarded triennially. The Alfred Woodhouse Scholarship of £35 and the Robert Woodhouse Prize of £10 for Practical Dental Surgery. Prizes and certificates are awarded by the lecturers for the best examinations in the subjects of their respective courses at the end of the summer and winter sessions. Fee for two years' hospital practice required by the curriculum, including lectures, £70 in one payment, or £73 10*s*. in two yearly instalments. The curriculum requires two years to be passed at a General Hospital ; the fee for this is about £68 5*s*. Both hospitals can be attended simultaneously. For the lectures in Chemistry and Physics for the Preliminary Science Examination £13 13*s*. The fee for the instruction in Dental Mechanics and the two years' hospital practice required by the curriculum is £200 if paid in one instalment, or 200 guineas if paid in three equal instalments. The fee for tuition in Dental Mechanics is £70 per annum ; for one year's hospital practice £28. The Winter Session opens on Oct. 1st.

University College Hospital Dental School, corner of Great Portland and Devonshire-streets, W.—This Hospital and School has recently been thoroughly reorganised, and is now fully equipped with all the most modern appliances. Students are entered as students of University College Hospital, and, as such, attend the classes of Chemistry, Physics, Anatomy, and Physiology in University College, which is a few minutes' walk from the Dental Department in Great Portland-street, hitherto known as the National Dental Hospital, the first Dental School to admit Women Students. Practical courses to comply with the R.C.S. curriculum are held. Clinical Lectures and Demonstrations are given, and each student on entering passes through a preliminary course under a demonstrator. Composition Fees : Comprising two years' Dental Mechanics, Anatomy, Physiology ; two years' Hospital Practice, Medicine, Surgery, and Dental Lectures (four years) : 1st year, £56 ; 2nd year, £84 ; 3rd year, £64 ; 4th year, £32. Total, £236. Medical Men : Two years' Mechanics, and Dental Practice and Lectures : 1st year, £102 6*s*. ; 2nd year, £70. Total, £172 6*s*. For a six years' course of medical and dental education comprising the whole of the dental curriculum and the curriculum for the M.R.C.S., L.R.C.P. diplomas : 1st year, £91 ; 2nd year, £70 ; 3rd year, £73 ; 4th year, £60 ; 5th year, £73 ; 6th year, £49 ; total, £416, in six instalments payable in advance.

Guy's Hospital.—The work of the Dental Department begins daily at 9 A.M. both in the extraction rooms and in the conservation room. The Extraction Rooms : There is ample accommodation for ordinary extractions and anæsthetic extractions, together with waiting- and retiring-rooms. Patients are admitted between 8.45 and 9.30 A.M., and are seen by the dental surgeon for the day, the staff demonstrator, the dental house surgeon, and the dressers. The Conservation Room is open from 9 A.M. till 5 P.M. It has a floor space of over 6000 square feet, and affords accommodation for about 100 dental chairs. with the necessary equipment of the most modern type, for the use of the Dressers, who, under the supervision of the Staff, perform the various operations of Dental Surgery. The members of the staff attend every morning and afternoon to give demonstrations and otherwise assist students in their work in the Conservation Room and Prosthetic Laboratory. The Probationers' Laboratory is supervised by three of the staff demonstrators, and instruction is given in operative dentistry on a " mannikin " to students during their first three months of clinical study. Students in Dental Prosthetics are received, and a graded. systematic, and full course of instruction, extending over two years, is carried out under the supervision of the Director of the Prosthetic Laboratory, assisted by two demonstrators and five mechanics. Dental students have the opportunity of attending at this hospital the whole course of instruction required by the examining board for the B.D.S. Lond. or L.D.S. Eng.—viz., the complete course in dental prosthetics, the special lectures and practice of the Dental Department, and the general lectures and practice of the Medical School. The fees for these two courses may be paid separately or together, or they may be combined with the fees required to be paid for the course for a medical diploma. Students who enter for a medical as well as a dental diploma are allowed to pursue their study of Dentistry during any period of their medical course most convenient to themselves without further charge. Two Entrance Scholarships are awarded in September, a War Memorial Scholarship in Arts of the annual value of £40 for four years; and a Science Scholarship of the value of £40 per annum for not more than four years. Prizes of the aggregate value of £40 are awarded for general proficiency and for skill in Operative Dentistry. The Newland-Pedley Gold Medal for Operative Dentistry is also awarded annually. Dental students are eligible for admission to the Residential College and enjoy the privileges of students in the Medical School. Application should be made to the Dean of the Medical School.

London Hospital.—This school is a part of the London Hospital and Medical College, and is fully equipped on the most modern lines and with the latest appliances. It provides a complete curriculum in all subjects for the B.D.S. Degree and for the L.D.S. Diploma, and is admirably adapted for the purpose of teaching. The Conservation Room is well lighted and ventilated and fitted with pump chairs of the latest pattern; the fountain spittoons at many of the chairs have been specially designed. Each spittoon has attached to it a saliva ejector, hot and cold water, compressed air, gas and electric current, also a swing bracket to carry the students' cabinet. Electric sterilisers are supplied in each department and motor engines where required. The School possesses in addition to the Theatres, Laboratories and Museums in the College, a special Museum of Dental Anatomy and Surgery, Operative Dentistry, Prosthetic and Extraction Rooms, and Laboratories for Practical Dental Metallurgy and Dental Prosthesis. A systematic course of instruction in Dental Prosthesis is arranged for pupils. The up-to-date Laboratory contains every modern apparatus and is in charge of a skilled curator and his assistants. Connected with the Medical College and Dental School are a Library, Athenæum, Clubs' Union, Dining Hall with moderate tariff, Students' Hostel, and an Athletic Ground. For full particulars as to fees and course of study advised apply to the Dean, Prof. William Wright, who will be glad to make arrangements for anyone wishing to see the Dental School and Medical College.

London (Royal Free Hospital) School of Medicine for Women.—Full courses are arranged for women students, in conjunction with the Royal Dental Hospital, Leicester-square, for the study of dentistry, and in preparation for the B.D.S. Degree of the University of London and the Licence in Dental Surgery of the Royal College of Surgeons of England, at the London (Royal Free Hospital) School of Medicine for Women.

PROVINCIAL.

Birmingham Dental Hospital, Great Charles-street.—Dean: Mr. W. T. Madin. The Dental Hospital was founded in 1858, and was recognised by the Royal College of Surgeons in 1880 for the teaching of Dental Students. Having an annual attendance of about 21,000 patients, it affords every advantage for students about to enter the profession to acquire a thorough practical knowledge, as required by the Medical Council. The present Hospital was opened on July 6th, 1905. It has accommodation for 50 students. The equipment is in accordance with the most modern requirements for the efficient teaching and practice of Dental Surgery. The operations performed annually average 41,000, including 9000 gold and other fillings, and many cases of crowns, bridges, porcelain inlays, and regulations. By arrangements with the Birmingham University and with the General and Queen's Hospitals the entire course of Lectures, Hospital Practice, &c., may be completed for an inclusive fee of £144 4*s.* 6*d.*, or including Mechanical Pupilage, £255 15*s.* 9*d.*, inclusive of Examination fees for L.D.S. Birm. The instruments and materials necessary for Hospital Practice cost about £45. The Composition Fee for the courses required for the L.D.S. of the University, or any of the Corporations alone, is £75, payable in two annual instalments at the commencement of the first and second years; that for the courses required for the L.D.S. and the Degree in Dentistry of the University is £93 15*s.*; that for the L.D.S. in combination with the M.R.C.S. and L.R.C.P. is £115; and that for the M.B., Ch.B., and B.D.S. is £120. All of these composition fees are payable in two annual instalments at the commencement of the first and second years. Each of these fees covers the cost of the courses given at the University for the qualifications indicated, but does not include fees for Hospital teaching, nor Pre-Dental year Chemistry and Physics. For two years' dental hospital practice the fee is £26 5*s.*, payable in two instalments of £13 2*s.* 6*d.* each at the commencement of the first and second (hospital) years respectively. For two years' mechanical pupilage, £111 11*s.* 3*d.*, which may be paid in two annual instalments of £65 12*s.* 6*d.* and £45 18*s.* 9*d.* respectively; mechanical pupils may join for a probationary period of one month, fee £6 11*s.* 3*d.*, which is deducted upon payment of the full amount. For general surgical hospital practice, lectures, and demonstrations: Surgery, two winters, £13 2*s.* 6*d.* One Entrance Scholarship is offered annually of the value of £37 10*s.* It is awarded to the student who, entering for the Dental Degree of the University in October, or having entered not earlier than the previous April, shall pass the best examination in the subjects studied during his apprenticeship. Candidates must be under the age of 21 years. Application for admission, together with a certificate of birth, must be sent to the Dean of the Medical Faculty, Mr. William F. Haslam, on or before Oct. 15th.

Leeds University School of Dentistry.—The School of Dentistry is adequately equipped to provide for the complete training of the dental student. The School forms a part of the Leeds School of Medicine, whilst the instruction in clinical and mechanical dentistry is carried out in the Dental Hospital at the General Infirmary. The courses of study are mainly designed to meet the requirements of the B.Ch.D. and L.D.S. Leeds, but every opportunity is afforded to students preparing for the degrees or diplomas of other licensing bodies. Full-time demonstrators give the instruction in clinical dental surgery and prosthetic dentistry, which is carried out under the supervision and direction of members of the Honorary Staff, two of whom are in attendance each day. Special facilities are provided for instruction in Orthodontia and Dental Radiography. Prizes are offered for competition to pupils and students in their respective years of study. Communications should be addressed to the Warden, School of Dentistry, The University, Leeds, from whom a prospectus may be obtained.

Dental Hospital of Manchester.—This hospital is in association for teaching purposes with the University of Manchester and the Royal Infirmary, and is in the centre of a very large population. Courses of study are provided to meet the requirements of the various examining bodies, including those of the University of Manchester for the qualifications L.D.S. and B.D.S., and the L.D.S. of the Royal College of Surgeons of England. Clinical instruction is given in Dental Prosthetics, Operative Dentistry, Diagnosis and Extraction, Orthodontics, Dental Surgery, Radiography, and Anæsthetics by specially appointed Clinical Teachers.

For the whole course of hospital instruction for the L.D.S. (including two years' mechanical training) the fee is £131 5*s*., paid in instalments. For the two years' Operative Course only, £26 5*s*., paid in two instalments. For the whole course of hospital instruction for the B.D.S. degree (including mechanical training), £168, paid in instalments. Additional practice in Dental Mechanics may be taken by pupils who have already received their mechanical training elsewhere, at a fee of £36 15*s*. for six months. All the courses of instruction are open to women students. Copies of the Prospectus will be forwarded on application to Mr. J. Hilditch Mathews, Dean.

Newcastle-upon-Tyne Dental Hospital and School.—This hospital is centrally situated (within five minutes of the various colleges, infirmary, and railway station); the rooms are well lighted and thoroughly equipped for carrying on the work. Dental surgeons and an anæsthetist attend each morning. A tutorial dental surgeon and a prosthetic tutor is also in attendance. The Composition Fee for the special Dental Lectures and Dental Hospital Practice is £60 4*s*. if paid in one sum, or £62 6*s*. if paid in two instalments of £31 3*s*. The Composition Fee for the Lectures at the Colleges of Medicine and Science is £57 10*s*.; in addition to this there is a library and an athletic fee. The fee for General Hospital Practice at the Royal Victoria Infirmary, Newcastle-upon-Tyne, is £23 2*s*. Medals and Certificates of Merit are granted to students showing certain standards of proficiency in the various classes at the Dental School. The prospectus of the Dental Hospital and School, containing full information, may be obtained from either Mr. J. T. Jameson, 12, Windsor-crescent, Newcastle-upon-Tyne, Dean, or Mr. James Coltman, 13, Ellison-place, Newcastle-upon-Tyne, Vice-Dean.

Devon and Exeter Dental Hospital, 24, Southernhay West, Exeter.—Established 1880.—The hospital is open on Mondays, Tuesdays, Wednesdays, Thursdays, Fridays, and Saturdays, and patients are admitted between the hours of 9.30 and 11 A.M. Students attend the practice of the hospital under the control of the medical officers. Honorary treasurer, Mr. J. M. Ackland; secretary, Mr. Albert G. Littlejohn.

SCOTLAND.

The Incorporated Edinburgh Dental Hospital and School.—The Edinburgh Dental Hospital and School is located in spacious and well-equipped buildings at 30, 31, and 32, Chambers-street, and offers special advantages to dental students. The General Courses required for the Dental Diploma may be taken in the Medical School of the Royal Colleges of Physicians and Surgeons or in the University schools. The general hospital attendance and clinical instruction are taken at the Royal Infirmary. The University, Medical Schools, and Royal Infirmary are within three minutes' walk of the Dental Hospital. The special courses are taken in the hospital. The Dental Hospital practice, extending over two years, affords a student ample opportunity for a full acquaintance with every branch of dentistry. The hospital admits a limited number of indentured pupils. They receive their instruction in Mechanical Dentistry concurrently with the general and special courses. A premium of 60 guineas is payable with each such pupil. The practice and lectures of the hospital are recognised by, and qualify for, all the Licensing Boards. The cost of the hospital outfit of instruments is included in the Dental Hospital fee of £42. The minimum cost of classes and Diploma for the whole course of dental instruction amounts to £98 17*s*. Those students who desire to take a Medical and Surgical Diploma in addition to the L.D.S. have in this school admirable facilities for so doing. The triple qualification of the Royal College of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow is recommended. The minimum cost of Professional Education, the Triple Qualification, and the Licence n Dental Surgery amounts to £172 19*s*. The Higher Dental Diploma (H.D.D.) of the Royal College of Surgeons affords an opportunity of obtaining a higher qualification subsequent to registration. The Prospectus, with full information, may be obtained by application to the Dean or the Assistant Secretary.

Incorporated Glasgow Dental Hospital, 158, Renfrew-street and 15, Dalhousie-street, Glasgow.—The School is open to Men and Women Students, and Lectures are given on Dental Surgery, Operative Dental Surgery, Orthodontia, Dental Anatomy and Physiology, Pathology, Dental Histology, Dental Mechanics, Crown and Bridge work, Dental Metallurgy, Dental Bacteriology, and Anæsthetics. A new Radiography department has been added. Lectures on general subjects required for Dentistry may be taken at the University or at one of the extramural schools where special provision is made for Dental Students. Composition fee for two years' Hospital Practice and Lectures special to Dentistry, £50 on entry, or in two instalments of £31 10*s*. and £21. A new mechanical laboratory with bench accommodation for 60 pupils and fully equipped with the most modern appliances for teaching practical dental mechanics has recently been added. Fee for two years' tuition, £63, or in two instalments. Full information may be had on application to the Dean.

Glasgow Royal Infirmary (Dental Department).—Mr. W. R. Taylor attends at the Royal Infirmary at 9 A.M. on Wednesdays and other days as arranged. The following course in the curriculum can be taken at St. Mungo's College: Anatomy, six months; Practical Anatomy, nine months; Physiology, six months; Chemistry, six months; Practical Chemistry with Metallurgy, three months; Surgery, six months; Medicine, six months; Materia Medica, three months; Clinical Surgery, six months; Dental Surgery, six months, and attendance for two years on the dental department of the hospital.

IRELAND.

Incorporated Dental Hospital of Ireland, Lincoln-place, Dublin.—All Dental Students who have passed their First Dental Examination in the Royal College of Surgeons in Ireland (or an equivalent examination or examinations) are admissible to the Clinical Instruction of the Hospital. In addition to Clinical Instruction and Special Demonstrations, courses of lectures are given at the hospital on Dental Surgery and Pathology, Mechanical Dentistry, the Administration of Anæsthetics, Orthodontia, Dental Anatomy, and Dental Materia Medica, and instruction in Anæsthetics. Fees: Hospital Practice (each year), £18 18*s*.; Lectures, £5 5*s*. The course in practical Dental Mechanics can be taken in the Hospital Laboratory. Further particulars can be obtained from the Dean.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

K. V. Francis to be Surg. Lt.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. St. G. B. D. Gray (late R.N.V.R., temp.) to be Surg. Lt. on Permanent List.

ROYAL ARMY MEDICAL CORPS.

Maj. J. W. S. Seccombe retires on ret. pay.

The undermentioned Maj.-Gens., late R.A.M.C., are appointed Hon. Surgs. to The King: H. A. Hinge, C.B., C.M.G., D.S.O., vice Maj.-Gen. S. G. Moores, C.B., C.M.G., late R.A.M.C., retd., and C. E. Pollock, C.B., C.B.E., D.S.O., vice Lt.-Gen. Sir T. H. J. C. Goodwin, K.C.B., C.M.G., D.S.O., late R.A.M.C., retd.

ARMY RESERVE OF OFFICERS.

Col. E. H. Condon, late R.A.M.C., having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Maj. A. H. Falkner relinquishes his commn. and retains the rank of Maj.

TERRITORIAL ARMY RESERVE.

The following having attained the age limit are retired: Lt.-Cols. J. C. Renton and Sir S. J. Sharkey (and retain the rank of Lt.-Col.); Majs. J. J. Cox (retains the rank of Maj.), and G. R. Swinhoe (retains the rank of Maj. and is permitted to wear the prescribed uniform); Capt. J. C. McClure (retains the rank of Capt.).

Capts. A. T. Swan and J. C. Stewart relinquish their commns. and retain the rank of Capt.

ROYAL AIR FORCE.

Flight Lt. H. L. Burton is granted a permanent commission.

INDIAN MEDICAL SERVICE.

Capts. E. S. Goss, C. J. Stocker, A. W. Duncan, L. F. Brandenbourg, and E. A. Penny to be Majs.

DEATHS IN THE SERVICES.

Surgeon-Commander Alec Bedingfield Marsh, R.N., surgeon specialist at the Royal Naval Hospital, Haslar, in diseases of the ear, throat, and nose, died at the age of 46 on Sept. 7th. He was the son of the late Mr. Henry Marsh, Paymaster-in-Chief, R.N., graduated in arts at Oxford in 1899, and qualified with the L.R.C.P., L.R.C.S. Edin., and the L.R.F.P.S. Glasg. with honours in 1903. After serving as assistant medical officer at the County Asylum, Winwick, near Warrington, he joined the Royal Navy in 1904. He served with the Prince of Wales in H.M.S. *Hindustan* and with the Duke of York in H.M.S. *Collingwood* at the outbreak of the war, and was afterwards with the Royal Naval Air Wing at Grantham. During 1919 he served in connexion with the evacuation of Russian refugees on the Black Sea, developing lung trouble from which he never completely recovered. He leaves a widow and two young children.

Surgeon-Colonel William Thomas Martin, A.M.S., retired, died at Bournemouth on Sept. 15th in his eighty-second year. He was a graduate of the old Queen's University of Ireland, where he obtained the gold medal in 1859. He received his first commission in the Army in 1863 and served with the Abyssinian expedition of 1867 and was present at the capture of Magdala (mentioned in despatches and medal). He also served with the Burmese expedition of 1885–87 (medal with clasp). Surgeon-Colonel Martin retired in 1896.

Correspondence.

"Audi alteram partem."

OPHTHALMOLOGICAL TRAINING FOR MEDICAL STUDENTS.

To the Editor of THE LANCET.

SIR,—The letter from Dr. Ernest Thomson in your issue of Sept. 1st seems to me to merit attention. The experience which I gained in teaching large numbers of undergraduates for many years has brought me to the opinion that Dr. Thomson is fundamentally right. Every effort should be made to limit the course to those parts of the subject which are of use to physicians and surgeons and practitioners as means of diagnosis. During all the years that I was teaching I endeavoured to give every student facilities for learning how to see the fundus oculi both by the direct and indirect methods, and generally availed myself of the help of a demonstrator to superintend the work in the dark-room.

No student should be allowed to qualify for registration on the Medical Register who cannot explore the fundus. I have known students who have been through an ophthalmic course without ever having had the opportunity of seeing an ophthalmoscope used. Some of them had seen pictures of the fundus in health and disease thrown on a screen by a projection lantern, but had never seen the ophthalmoscope used. Such a course should certainly not be recognised either for graduation or qualification. I also invariably laid special stress on the taking of fields of vision, the analysis of diplopia, the testing of the pupillary reflexes, and the estimation of visual acuteness. In other words, I did my best to make the students acquainted with those parts of ophthalmic study which may be helpful in localisation. In addition to this instruction, I always discussed in considerable detail iritis, corneal ulceration, interstitial keratitis, glaucoma, and cataract. I feel that nothing more should be attempted in the case of undergraduates. It seems to me that the above subjects are the essentially useful, and that the 20 meetings to which the qualifying course was by regulation supposed to extend—my own course always was one of 40 meetings—was too short to take in anything more than the above subjects, and even these could only be dealt with in an elementary fashion.

In Sir George Newman's lately published report there is a paragraph from which the casual reader might infer that the suggestion to teach the undergraduate the use of the ophthalmoscope is a new one, although, in fact, prominence has been given to that subject in almost every elementary course in the United Kingdom for the last 30 or 40 years. Undoubtedly there were, as I have already indicated, and possibly still are, a few courses in which no opportunity was, or is, given to the students to practise with the ophthalmoscope, but that has been for many years the exception. Personally, I think that instruction deficient in this respect should not be considered as qualifying. It is obvious that the consulting ophthalmic surgeon of a large general hospital should be in close contact both with the physicians and surgeons of the hospital. When the consulting ophthalmic surgeon takes his duties seriously such consultations may be of the greatest value; but I have known one large hospital which had a consulting ophthalmic surgeon who never gave a consultation, but always allowed the work to be done by an assistant, and occasionally by a very incompetent one.

In my own life-time that august body, the General Medical Council, has perpetrated at least two jokes: it ordained that physics should be taught in 50 meetings; it ordained that ophthalmology should be taught in 20.—I am, Sir, yours faithfully,

Glasgow, Sept. 17th, 1923. FREELAND FERGUS.

PATHOLOGICAL DEPARTMENTS.

To the Editor of THE LANCET.

SIR,—The leading article on this subject in your issue of Sept. 8th made special reference to the conditions which exist in Leeds. Since the matter has had some publicity, I desire to add to what has already been written in your columns on this subject.

You remark particularly on the fact that the posts of professor of bacteriology and city bacteriologist have been combined here. While admitting that economy has been a considerable factor in connexion with that arrangement, and that it is not in all respects an ideal one, I think it is desirable to state, in justice to those who have been responsible for this arrangement, that economy has not been the only advantage considered. An arrangement such as the existing one enables a university bacteriological laboratory to carry a considerably larger staff than would otherwise be possible, and amongst these the work is shared out. As a result the public health work of the city is carried out by a group of men who spend their time partly in teaching, partly in research, and partly on routine examinations, instead of being done by one or at most two men, who tend to be deluged with routine examinations. Where the appointment is entirely a municipal one, the city bacteriologist being on a fixed salary, there is a tendency to send specimens for examination without stint, and the bacteriologist may be forced to delegate his work unduly or to adopt rather precarious short cuts. On the other system of payments for specimens examined, there is likely to be a more discriminate demand for examinations, and as soon as there is a real and necessary increase in the work required the university is automatically enabled to increase the staff of its bacteriological department. Of course it might be argued that necessary examinations are cut out on the score of economy. This, if it were the case, would, I think, be the strongest objection to the existing system.

The mental outlook in a laboratory where a good deal of teaching and research are going on should be wider and the methods more enterprising than in a laboratory solely or mainly devoted to routine, and to the extent that that is the case the municipal bacteriology should be more thoroughly done in a university laboratory. On the other hand, the weak points in a scheme, such as that existing at Leeds, are as you suggest: (1) That the time of the heads of the university department concerned may be too much absorbed with administrative duties, and (2) that the health of the city is not the first and only professional interest of the city bacteriologist. I believe, however, that the argument for and against an arrangement such as that existing in Leeds are more evenly balanced than you have supposed.

In a letter on the Status of Pathology in the same issue of your journal Dr. C. Powell White suggests, amongst other proposals, that it is desirable that some university should establish a course of training for pathologists of a standard equivalent to that of the honours courses in other branches of science. As far as bacteriology is concerned at Leeds this has been done. A short course diploma in bacteriology has not been arranged as at Manchester; but bacteriology has been made a principal subject for an ordinary or honours B.Sc. in pure science.

I am, Sir, yours faithfully,
James Walter McLeod,
Professor of Bacteriology, University of Leeds.

Sept. 12th, 1923.

WELLCOME BUREAU OF SCIENTIFIC RESEARCH.

A CORRECTION.

To the Editor of The Lancet.

Sir,—I notice that in The Lancet of Sept. 15th you state that I have resigned my post at the above Bureau *to take up other important duties* (the italics are mine). The wording is unfortunate, as it might lead anyone to suppose that my resignation is due to the fact that I have obtained another position and am relinquishing my duties here on that account. Such is not the case, and I would ask you to be good enough to insert this explanation in your next issue. I realise that the words I have italicised may merely be the expression of a pious hope, a hope I devoutly share, but they are certainly liable to misinterpretation. Hence my request.

I am, Sir, yours faithfully,

Sept. 14th, 1923. Andrew Balfour.

LILLIPUTIAN DOSAGE.

To the Editor of The Lancet.

Sir,—In your issue of Sept. 15th (p. 574) appears an annotation on a paper of Prof. Viton, under the heading "Lilliputian Tuberculin Dosage." At the end of the note you add: "Prof. Viton does not say whether he has or has not carried out control tests with a 0·25 per cent. solution of carbolic acid alone." It seems to me that a consideration of the figures given makes it clear that, at any rate with the higher dilutions, the effect can only be due to the carbolic acid.

If we assume Millikan's value of $6{\cdot}06 \times 10^{23}$ for the number of molecules in a gram molecule, and assume (*a*) that the original tuberculin is *pure* active principle; (*b*) that the molecular weight of this active principle is 200 (this is decidedly below the true value), ve have $\frac{6{\cdot}06 \times 10^{23}}{200}$ molecules in 1 g. of the tuberculin. n the dilution given in The Lancet, this is diluted to 0^{27} c.cm. We therefore have $\frac{6{\cdot}06 \times 10^{23}}{200} \times \frac{1}{10^{27}}$ molecules of tuberculin per c.cin. at the dilution given. This is, statistically, only 0·000003 mols. per c.cm.—i.e., approximately every 300,000th c.cm. contains one molecule of active principle.

Any impurity of the original tuberculin, or any value for its molecular weight over 200 makes this dilution even greater.—I am, Sir, yours faithfully,

Manchester, Sept. 17th, 1923. E. N. Allott.

Medical News.

London Hospital Medical College.—A lecture on the Treatment of Diabetes Mellitus with Insulin will be delivered by Dr. Otto F. F. Leyton on Oct. 15th, at 4.15 P.M., in the Anatomical Theatre of the College. The lecture is intended for senior students of the hospital and postgraduates.

Society for the Study of Inebriety.—The tenth Norman Kerr Memorial Lecture on Drug Addiction will be delivered by Sir William Willcox, on Oct. 9th, at 4 P.M., in the Hall of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W. 1.

Royal Institute of Public Health.—The next Congress will be held in Bordeaux, France, from Wednesday, June 4th, to Monday, the 9th, 1924 (Whitsuntide). The Congress will be under the Presidency of Lord Burnham and will be conducted in the following sections: (*a*) State Medicine and Municipal Hygiene—President, Sir Humphry Rolleston; (*b*) Naval, Military, and Air—President, Surg. Vice-Admiral Joseph Chambers; (*c*) Industrial Hygiene—President, Sir Thomas Oliver; (*d*) Tropical Diseases—President, Sir Ronald Ross, F.R.S.; (*e*) Pathology, Bacteriology, and Biochemistry—President, Sir John Bland-Sutton; (*f*) Women and Public Health—President, Lady Crewe. The meetings will be held in the University of Bordeaux and the Council will be pleased to welcome anyone interested in public health work. Further particulars can be obtained on application to the Secretary, 37, Russell-square, London, W.C. 1.

Royal Sanitary Institute.—A prospectus of the lectures and demonstrations to be delivered during the autumn term has been issued, and can be obtained from the offices, 90, Buckingham Palace-road, London, S.W. 1. An introductory lecture will be given to the students of the several courses by Prof. H. R. Kenwood, Deputy Chairman of the Council, on Monday, Sept. 24th, at 5.30 P.M., in the Institute. The sanitary officers' course comprises the subjects scheduled for the examination of the Institute and the Sanitary Inspectors' Examination Board. The practical training for meat and food inspectors includes the inspection of meat at a cattle market, with demonstrations on live cattle and sheep, slaughtering and dressing of animals, &c. The lectures for health visitors and child welfare workers are arranged as a preparation for the health visitors' examination of the Institute. This course is open to all students who wish to attend, but only those who hold the nursing and midwifery qualification recognised by the Board of Education can be admitted to the examination.

Maudsley Hospital.—A course of lectures and practical courses of instruction for a diploma in Psychological Medicine (Part II.) will be held at this hospital, Denmark Hill, London, S.E., during the session. Eight lectures on Morbid Psychology will be delivered by Dr. Edward Mapother on Mondays at 2.30 P.M. and 4.30 P.M., commencing Oct. 8th; eight lectures on the Psychoneuroses, by Dr. Bernard Hart, on Mondays at 3.30 P.M. and 5.30 P.M., commencing Nov. 5th; six lectures on the Pathology of Mental Diseases, including Brain Syphilis, its Symptomatology and Treatment, by Sir Frederick Mott, F.R.S., on Tuesdays at 4.30 P.M., commencing Nov. 6th; five lectures on the Legal Relationships of Insanity and Treatment, by Dr. C. Hubert Bond, on Oct. 9th, 11th, 16th, 23rd, and 25th, at 4.30 P.M.; eight lectures on the Practical Aspect of Mental Deficiency, by Dr. F. C. Shrubsall, on Wednesdays at 2.30 P.M., commencing Oct. 10th, and on Tuesdays at 2.30 P.M., commencing Nov. 6th; six lectures on Crime and Insanity, by Dr. W. C. Sullivan, on Wednesdays at 4.30 P.M., commencing Oct. 10th, and on Thursdays at 4.30 P.M., commencing Nov. 8th and 15th; six lectures in Clinical Psychiatry, by Dr. Mapother, on Wednesdays at 2.30 P.M., commencing on Nov. 7th; twelve Clinical Demonstrations in Neurology, by Sir Frederick Mott, and Dr. F. L. Golla, on Thursdays at 2.30 P.M., commencing Oct. 11th. The first six demonstrations will be given by Sir Frederick Mott at Camberwell Infirmary; the second six will be given by Dr. Golla at the Hospital for Paralysis and Epilepsy, Maida Vale, on Thursdays at 2.30 P.M., commencing Nov. 22nd. Inquiries as to lectures, &c., should be addressed to the Director of the Pathological Laboratory at the hospital.

Radcliffe Infirmary, Oxford.—A post-graduate course will be held as usual this year in the week Oct. 1st–6th. There will be morning clinics and demonstrations, and in the afternoon two 1½ hour sessions. A detailed programme will be sent on application to Dr. W. T. Collier, 48, Woodstock-road, Oxford, or Dr. Hugh Whitelocke, 6, Banbury-road, Oxford, joint hon. secretaries.

Sociological Society.—A course of six lectures on the Bearing of Psycho-Analysis upon Sociological Problems will be held at Caxton Hall, Westminster, on consecutive Tuesdays, beginning Tuesday, Oct. 9th, at 8.30 P.M., when Dr. Ernest Jones will give an introductory lecture. Subsequent lectures, entitled "Man the Individual," "The Family," "Politics," "Education," "Vocation," will be given by Dr. James Glover, Mr. J. C. Flugel, Dr. M. D. Eder, Miss Barbara Low, and Miss E. Sharpe respectively. Applications for tickets should be made to the Secretary, Psycho-Analytical Lecture-Course, Leplay House, 65, Belgrave-road, Victoria, London, S.W. 1.

North-East London Clinical Society.—The programme for the session 1923–24 is as follows: On Oct. 4th, at 4.15 P.M., Dr. G. F. Still will give the opening lecture on Common Errors of Diagnosis in Diseases of Children. On the 11th the annual dinner will be held at The Prince of Wales's Hospital, Tottenham, at 8 P.M. for 8.15 P.M. On Nov. 7th Dr. F. H. Kyngdon on Early Experiences in Practice, followed by a discussion and exhibition of cases by members of the Society. On Dec. 6th Mr. E. M. Atkinson will read a paper on the Significance of Hæmaturia and its Investigation. On Jan. 2nd, 1924, Dr. T. Rushbrooke will give Reminiscences from General Practice; and on Feb. 7th Mr. W. Ibbotson will discuss the Relation of the Central Nervous System to the Ear, Nose, and Throat, in Health and Disease. On March 5th a paper will be read by Dr. F. J. Tresilian on Old Drugs and New; and on April 3rd one by Dr. L. R. Yealland on the Rôle of Neurology in General Practice. On May 7th Dr. H. C. Samuel will speak on Some Common Errors in the Diagnosis and Treatment of Diseases of the Skin, and on June 5th Mr. N. B. Fleming will discuss Ocular Manifestations of Disease Elsewhere. The meetings will be held at 4.15 P.M. at the Prince of Wales's Hospital, Tottenham.

Medical Society of London.—The syllabus of the first half of the session 1923–24 has now been issued. On Oct. 8th, at 8 P.M., the annual general meeting will be held, followed at 8.30 P.M. by an ordinary meeting, when Dr. Herbert Spencer will give his presidential address on Some Changes in Obstetric Practice since the Foundation of the Medical Society of London. On Oct. 22nd, at 8.30 P.M., there will be a clinical evening, with an exhibition of cases and radiograms. On Nov. 12th, at 8.30 P.M., a discussion on Constipation—its Causes, Results and Treatment from the General Practitioner's Point of View will be introduced by Dr. H. Des Vœux, followed by Dr. Walter Broadbent, Dr. Chittenden Bridges, Dr. D. M. Barcroft, Dr. W. W. Stocker, Dr. Edward Furber, Dr. Percy Spurgin, Dr. Moreland McCrea, and others. On Nov. 26th, at 8.30 P.M., a discussion on the Treatment of Acute Suppurative General Peritonitis will be introduced by Mr. Sampson Handley, followed by Mr. James Berry, Sir Cuthbert Wallace, Mr. Garnett Wright, Mr. H. Carson, Mr. R. P. Rowlands, Mr. V. Z. Cope, and others. On Dec. 10th, at 8.30 P.M., a discussion on Intracranial Hæmorrhage in New-born Children, its Pathology, Effects, Treatment, and Results, will be introduced by Mr. Eardley Holland and Dr. H. Charles Cameron, followed by Dr. Farquhar Buzzard, Mr. Laming Evans, Dr. Sidney Owen, Mr. H. A. T. Fairbank, Dr. J. B. Mennell, Dr. L. G. Phillips, and Dr. E. Bellis Clayton.—The Lettsomian lectures on the Treatment of Pulmonary Tuberculosis will be delivered in February and March, 1924, by Dr. R. A. Young, and the annual oration will be delivered in May, 1924, by Mr. Wilfred Trotter. The hon. secretaries for the year are Mr. T. P. Legg and Prof. F. Langmead; the house of the society is at 11, Chandos-street, Cavendish-square, W. 1.

Manchester's Public Health Committee.—The multifarious activities of the sanitary section are set forth in a report recently issued covering the period from April 1st, 1922, to March 31st, 1923. There are 28 sets of tables and 24 sections dealing with subjects ranging from complaints made by the medical officer of health, the police, and the public (the number of complaints of nuisance dealt with was 10,274), to inspection of drains, the abatement of nuisances of various kinds—dairies and milkshops, ice-cream manufacture (510 in number), public lavatories, workshops, canal boats, unhealthy dwellings, offensive trades, and adulteration of food and drugs. Houses let in lodgings or occupied by more than one family number 2403, to which 23,369 day and 302 night visits were made. The number of infectious cases dealt with by the inspectors was 7974. Four inspectors were specially employed to deal with the nuisance arising from the emission of black smoke, and 111 cases were reported where the emission had been two minutes or more in the half hour's observation. Sixty-seven cases were referred to the justices and in the remaining cases the offenders were cautioned. The bakehouses number 642, and of these 47 are situated in basement premises. As regards the adulteration of food and drugs the percentage of samples adulterated has increased from 2·95 last year to 3·40 this year. The highest percentage of adulteration (12·82 per cent.) seems to obtain in mineral waters, cordials, &c., followed by milk, 7·7. The inspector for carrying out the Canal Boats Acts inspected 1899 boats during the year. The number of insanitary dwellings certified was 55. An average of 442 lodgers per night were accommodated at the Municipal Lodging House for Men (cubicles 467) and 195 per night of women at Ashton House (cubicles 210).

Presentation to a Medical Man.—Dr. Adolph Bronner, who has been for 34 years honorary surgeon to the Royal Eye and Ear Hospital, Bradford, and whose father was one of the founders of the hospital, was presented on his retirement from the post, by the Lord Mayor, Alderman T. Snowden, in the Council Chamber on Sept. 13th, with two travelling bags and a gold cigarette case. A tablet recording Dr. Bronner's services has also been placed in the hospital. The surplus of the money subscribed was handed to Dr. Bronner, who expressed his intention of buying with it something useful for the institution with which he has been so long connected.

Financial Needs of Leeds Hospitals.—Owing to the fact that the Leeds Infirmary has a very heavy bank overdraft amounting to £54,500, and increasing at the rate of £60 a day, it has been determined to make a special appeal to the business establishments and trades of the city on behalf of the infirmary and the other three principal hospitals—the Hospital for Women and Children, Leeds Maternity Hospital, and the Public Dispensary. To this end the city has been divided into 20 areas, and every firm will be visited with a view to enlisting the financial aid of chiefs and staffs alike to liquidate the debt.

The late Dr. W. Case, J.P.—Dr. William Case, born at Aylsham, near Norwich, in 1863, died on July 30th at Durban after an operation. He had been Government District Surgeon at Harding, Alfred County, Natal, for 18 years. Educated at King's College Hospital, London, Dr. Case arrived in Natal in 1896. For a short period he undertook the duties of house surgeon at Grey's Hospital, Pietermaritzburg. He then became successively the Government District Surgeon at Eshowe, Zululand, Paulpietersburg, and finally at Harding, where he has practised since 1905. Dr. Case was a lover of sport, and was for three years president of the Alfred Company Agricultural Society. Much sympathy is felt for the widow and son, Mr. Leslie Case.

The late Dr. John McMurray.—The death of Dr. John McMurray took place at his residence at Bootle on Sept. 12th at the age of 66. After a distinguished medical career at Queen's College, Belfast, in the early 'eighties he took the M.Ch. and M.D. degrees of the Royal University of Ireland. He held several appointments as house surgeon and resident medical officer in institutions in Liverpool, and then settled in Bootle, where he was for a time honorary surgeon of the Bootle Borough Hospital. He was also a J.P. of the borough, and Mayor of Bootle in 1897–98. Dr. McMurray occupied a prominent position in the borough and served for years on the borough council; and his work as a medical man was mostly among the working classes with whom he was very popular for his kindly manner and his robust geniality. He was an enthusiastic Freemason, being P.M. of the Hamer Lodge in 1893.

Donations and Bequests.—By the will of the late Mr. R. Beck, of Swansea, the testator left, among other bequests, 3000 £1 5½ per cent. Cumulative Preference shares of Baldwins, Limited, to the Swansea General and Eye Hospital; 1000 such shares each to the Y.M.C.A., the Institution for the Blind, Swansea, and the Deaf and Dumb Institution; 500 each to the Discharged Prisoners' Aid Society, Swansea, and the Invalid Asylum, Stoke Newington, London, N. The residue of the estate, after certain family trusts have been made, will be divided into 100 parts—each roughly amounting to about £1000. This residue will be distributed among certain institutions, including 20 parts each to the Swansea University College and the Swansea General and Eye Hospital; 5 parts each to University College Hospital, London, Dr. Barnardo's Homes, and the National Benevolent Institution, London, E.; 3 parts to the Hospital for Women, Stoke Newington, London, N.; 2½ parts each to the Royal Wolverhampton Orphanage, the Glyn Vivian Blind Institution, the Royal National Lifeboat Institution, and the Children's Home, Bonner-road, Victoria Park, London.—Under the will of the late Mr. J. P

Bauer, of Manchester, the following among other bequests are made: £1000 to the Manchester Royal Infirmary, to endow a bed to be called the "James Bauer bed"; £100 each to St. Mary's and South Hospital, and Ancoats Hospital and Dispensary; and £50 each to the Manchester Jewish United Sisters Maternity Society, and the Manchester Jewish Kosher Kitchen at the Manchester Royal Infirmary.—Mr. Thomas Frederic Harrison, shipowner, of Liverpool and Windermere, left £500 each to the Westmorland County Hospital, Kendal, Liverpool Royal Infirmary, Liverpool Northern Hospital, Liverpool Southern Hospital; and £250 each to the Stanley Hospital, Liverpool, and the Children's Infirmary, Liverpool.—The Manchester Children's Hospital during the past month received donations to the amount of £1589, including £1388 from the Hospital Sunday Fund.—As a result of the garden party held in July over £500 have been handed over to the Lord Mayor of Manchester's Two Million Shillings' Fund for the city hospitals.

MEASUREMENT OF PROGRESS IN PUBLIC HEALTH.—A lecture with this title will be delivered by Sir Arthur Newsholme on Oct. 4th, at 5 P.M., at the London School of Economics and Political Science, Houghton-street, Aldwych, W.C. 1.

UNIVERSITY COLLEGE HOSPITAL.—Past and present students of the hospital will hold their annual dinner on Friday, Oct. 5th, at the Hotel Cecil. Tickets (12*s.* 6*d.*) can be obtained from Mr. Gwynne Williams and Dr. T. R. Elliott at University College Hospital Medical School.

FATAL ACCIDENT TO GALWAY MEDICAL MAN.—Dr. George O'Kelly, of Mountbellew, County Galway, was recently killed in a motor accident. While he was driving in answer to a medical call, a dog ran under his car and the steering gear went out of order. The car mounted a ditch and overturned on Dr. O'Kelly, killing him instantaneously. He had been medical officer of Mountbellew for 13 years, and was held in high respect.

FOREIGN DECORATION.—The King has given Dr. James Ferguson Lees, C.B.E., Director-General of the Egyptian Public Health Administration, His Majesty's Royal licence and authority to wear the Insignia of Grand Officer of the Order of the Nile, which decoration has been conferred upon him by the King of Egypt.

DUBLIN LABOUR DISPUTE AND SUPPLY OF DRUGS.—An impasse has arisen in regard to the supply of drugs to the Dublin Union. It appears that the contractors, a Dublin firm of manufacturers, have some dispute with their employees, and are at present employing non-union labour. When they delivered a supply of drugs to the union, certain of the employees of the guardians refused to handle them, and the drugs had to be removed by the contractors' men. The representatives of labour requested the guardians to purchase their drugs from a firm employing only union labour, and suggested the name of a Liverpool firm. The guardians, however, have no power to purchase otherwise than from their contractor, and the contract does not terminate until Sept. 30th. The net result appears to be that the patients in the union hospital are deprived of medicines.

A LINK WITH FLORENCE NIGHTINGALE.—Mr. Alfred George Wilkinson, M.R.C.S., L.S.A., who qualified in 1857 and who died at Northampton on Sept. 14th in his eighty-ninth year, was a student at Birmingham when the Crimean War broke out. He volunteered for service and served principally at the Barrack Hospital at Scutari, attending the wounded after the charge of the Light Brigade at Balaclava. Mr. Wilkinson had been in practice at Northampton since 1870 and three years ago was presented with a testimonial by his fellow-townsmen. He had been attending patients up to a week before he died and was confined to his bed for only four days.

THE LATE DR. WILLIAM WHITE, J.P.—Dr. White died suddenly at Hadfield on August 31st at the age of 72. A native of Laxton, Notts, where his forbears had resided for over 200 years, Dr. White was educated at Newark-on-Trent and at Aberdeen University, where he graduated M.B., C.M. in 1876, and M.D. in 1878 with honours. Dr. White practised for a few years at Wooley Bridge and in 1884 settled at Hadfield, where he spent the remainder of his busy and useful life. In 1911 he was chosen an Alderman of the Borough of Glossop, then Mayor for the year 1912–13, and Deputy Mayor for nine subsequent years. His services were specially valuable in all matters connected with sanitation and health; besides holding other offices he had been a Justice of the Peace from 1897. Dr. White was much loved in the district in which he worked for 40 years and his memory will long be cherished. Both his sons studied medicine at the University of Manchester, Captain White being killed in the war, while Dr. Charles Francis White is assistant medical officer at the Port of Liverpool.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, Sept. 24th.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

TUESDAY.—10 A.M., Mr. Steadman: Dental Dept. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Mr. Gibb: Eye Dept.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-urinary Dept.

FRIDAY.—10 A.M., Mr. Dudley Buxton: Dental Dept. 2 P.M., Dr. Burrell: Medical Out-patients. 2 P.M., Mr. Banks-Davis: Nose, Throat, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M. Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

ST. MARY'S HOSPITAL MEDICAL SCHOOL POST-GRADUATE COURSE.

SATURDAY, Sept. 29th.—10–11 A.M., Dr. C. L. Fitzwilliams: Early Diagnosis of Cancer of the Breast. 12–1 P.M., Mr. S. Maynard Smith: Chronic Pain in the Right Side of the Abdomen. 2–3 P.M., Sir William Willcox: Chronic Rheumatic Toxæmia. 3–4 P.M., Dr. R. Miller: Demonstration of Cases of Cœliac Disease.

SUNDAY, Sept. 30th.—10.30 A.M., Dr. C. M. Wilson: Investigation of Dyspepsia. The Treatment of Diabetes.

MANCHESTER FRENCH HOSPITAL, 24, Acomb-street, Whitworth Park, Manchester.

THURSDAY, Oct. 4th.—4.30 P.M., Dr. N. C. Haring: The Spahlinger and other Methods of Serum Treatment in Pulmonary Tuberculosis.

Oct. 11th.—Dr. A. C. Magian: The Treatment of Painful Menstruation.

Oct. 18th.—Mr. R. R. Kerr: The Surgery of Injured Fingers.

Oct. 25th.—Dr. A. C. Magian: The Treatment of Irregular Menstruation.

Appointments.

ECCLES, H. A., M.D. Lond., has been appointed House Physician to the Royal Infirmary, Sunderland.

SANDILAND, E. L., M.B., B.S. Lond., D.P.H., Medical Superintendent to the East Lancashire Tuberculosis Colony, Barrowmore Hall, near Chester.

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth Infirmary, &c.—H.S. £200.
Benenden (Kent) National Sanatorium.—Res. Asst. M.O. £250.
Bromley and Sevenoaks Rural District Councils.—M.O.H. £1000.
Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Three Registrars.
Epsom, The Manor.—Jun. Asst. M.O. £432.
Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and Asst. Cas. O. £50.
Ipswich County Borough.—Sen. Asst. M.O.H., &c. £600.
Kingston-upon-Hull City and County.—R.M.O. £400.
Leicester City.—Asst. Tuberculosis O. £600.
London County Mental Hospital Service.—Seventh Asst. M.O. £432.
London Jewish Hospital, Stepney Green, E.—Hon. Asst. P., Hon. S. Also Asst. to Out-Patients. £100.
Manchester Northern Hospital for Women and Children.—Hon. S.
Manchester Royal Infirmary.—R.M.O. £200.
Newcastle-on-Tyne Dispensary.—Hon. Phys.

Newcastle-upon-Tyne City Hospital for Infectious Diseases.—Res. Med. Asst. £350.

Nottingham Education Committee.—Jun. Asst. Med. Insp. £500.

Oswestry, Shropshire Orthopædic Hospital.—Res. Surg. O. £500. Two H.S.'s. £250.

Plaistow Fever Hospital, Samson-street, E.—Sen. Asst. M.O. £430.

Prince of Wales's General Hospital, Tottenham, N.—H.S. £150. H.P. £150. Also Jun. H.S. and Jun. H.P. £110 each.

Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.

South London Hospital for Women, Clapham Common, S.W.—Temp. Asst. P.

South Mimms, Barnet, Clare Hall Hospital and Sanatorium.—Asst. M.O. £350.

Staffordshire General Infirmary, Stafford.—H.P. £150.

Walsall General Hospital.—Sen. H.S. and Jun. H.S. £200 and £150 respectively.

West Bromwich and District Hospital.—Res. Asst. H.S. £180.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. H.S.'s. £150 and £100 respectively.

Wolverhampton and Staffordshire Hospital.—Res. M.O. £150.

York City Mental Hospital, Fulford.—Asst. M.O. £500.

The Chief Inspector of Factories, Home Office, S.W., announces a vacant appointment at Mid-Calder, Edinburgh.

Births, Marriages, and Deaths.

BIRTHS.

Broster.—On Sept. 11th, at Winn-road, Southampton, the wife of L. R. Broster, M.Ch., F.R.C.S., of a daughter.

Eason.—On Sept. 11th, at the Superintendent's House, Guy's Hospital, the wife of H. L. Eason, C.B., C.M.G., M.D., of a daughter.

Forrest.—On Sept. 13th, at 10, Coates-crescent, Edinburgh, the wife of A. W. Forrest, M.A., M.D., D.P.H., Public Health Department, Wandsworth, of a daughter.

McMorland.—On Sept. 13th, at Brookfield, Colyton, Devon, the wife of Dr. J. Bruce McMorland, of a daughter.

Walker.—On Sept. 8th, at Kuliang, China, the wife of Dr. Ronald R. Walker, of a son.

MARRIAGES.

Worger—Gaskins.—On August 20th, at The Church of The Sacred Heart, Burnham-on-Sea, William Worger, M.R.C.S., L.R.C.P., to Edith Gaskins, second daughter of A. A. A. Wotzel, Esq., O.B.E., of Belmont, Sutton, Surrey.

GOLDEN WEDDING.

Larkin—Wood.—On Sept. 17th, 1873, in the Choir of Saint Saviour's, Southwark (Southwark Cathedral), by the Revd. Samuel Benson, M.A., chaplain, assisted by the Revd. Daniel Moulhin, B.A., rector of Holy Trinity, Trinity-square, S.E., Jane Maria, second daughter of the late William Wood, M.R.C.S. Eng. and L.S.A. Lond., of Trinity-square, S.E., to Frederick George Larkin, F.R.C.S. Eng., L.R.C.P. & L.M. Edin., of Trinity-square, S.E., and Grove Park, Kent, youngest son of the late Richard Larkin, of Maypole, Hoath, near Canterbury.

DEATHS.

Farnell.—On Sept. 16th, suddenly, Henry Dawson Farnell, F.R.C.S., of Grasmere, Eastbourne, aged 71 years.

Jackson.—On Sept. 14th, at the Freemasons Hospital, London, John Charles Jackson, late Medical Officer for Health of Fulham, in his 71st year.

Manning.—On Sept. 12th, suddenly, in London, Joseph Vincent Manning, M.D., late of Bloemfontein, South Africa.

Martin.—On Sept. 15th, at Bournemouth, Surgeon-Colonel W. T. Martin, A.M.S., retd., in his 82nd year.

Norris.—On Sept. 9th, at Garmelow, Eccleshall, Edward Stacy Norris, M.A., M.B., late of Eton, aged 71.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

The late Mr. H. D. Farnell.—On Sept. 16th Eastbourne lost one of its oldest medical practitioners by the death of Dr. Henry Dawson Farnell. He had been in practice in the town since 1878, and was respected and esteemed by everyone with whom his work brought him in contact. Dr. Farnell was born at Salisbury 71 years ago. He studied medicine at University College, London, and became M.R.C.S. Eng. in 1874 and F.R.C.S. in 1885. For three years he was house surgeon at the Liverpool Northern Hospital, after which he settled at Eastbourne. He was one of the oldest members of the medical staff of the Princess Alice Memorial Hospital. In 1894 he was placed on the Commission of the Peace for the borough. During the war Dr. Farnell did much voluntary work at the local Red Cross Hospital, also at Summerdown Convalescent Camp, and was subsequently given the O.B.E. He married in 1881 Miss Mary Colgate, daughter of Mr. Robert Colgate, F.R.C.S., also of Eastbourne.

Notes, Comments, and Abstracts.

A MEDICAL STUDENT'S IMPRESSIONS OF SOME CONTINENTAL HOSPITALS AND THEIR METHODS.*

By G. E. C. Collis.

A party of some 17 senior medical students, representing universities in London, Edinburgh, Oxford, Manchester, Glasgow, Liverpool, and Leeds, undertook this autumn a three weeks' tour of the principal continental university towns. Our itinerary included Brussels, Leyden, Berlin, Dresden, Vienna, Prague, Munich, Zurich, and Paris; everywhere we were welcomed by local students and given facilities to inspect medical work. It might be of interest to record a few of the impressions we received, the points which in medical or surgical practice struck us as interesting, either because of their difference from or similarity to those in vogue in Great Britain. Of necessity such a tour precludes any detailed study of continental methods, but nevertheless a bird's-eye view can be gained of hospital accommodation and appliances, of the quantity and type of the clinical material, and most important of all, one meets the men who are working in these centres. Perhaps one's first observation is not the differences but the essential similarities which exist between British and foreign hospitals and medical men. The similarity of structure and routine of the former; of the type, mode of thought, and outlook of the latter.

Hospital Accommodation.

The hospitals visited varied from the new and as yet unoccupied premises of Leiden, which embody the accumulated experiences of European and American institutions, to the centuries old Salpêtrière in Paris, a transformed pre-revolutionary jail. The continental hospitals as a whole struck us as being much better supplied with gardens and surrounding parks than similar institutions in this country. There, however, the ward accommodation is much more restricted. In some places there is scarcely room to walk between the beds, and the centre of the floor is frequently occupied by beds back to back. Gymnasia containing mechanical appliances were very much in evidence in all the hospitals of German-speaking towns, especially Vienna, where there is a separate apparatus for both active and passive exercise of each group of muscles in the body.

A Treatment for Pelvic Exudates.

A form of treatment for pelvic exudates not in general use in this country was seen in Vienna. The patient is placed in the lithotomy position with the pelvis raised, and a rubber bag, resembling a small Champetier de Ribes's bag, containing 1 kgm. of metallic mercury, is inserted into the posterior fornix and left in position 10–15 minutes. Pressure of the bag combined with the respiratory movements of the patient give the effect of "internal massage." The treatment is repeated every two or three days. This mercury bag is also used to assist in the replacement of the retroverted uterus. The dorsal position is everywhere used for the examination of patients, the Sims very seldom.

In Leiden and Vienna we were shown the obstetric forceps designed by Kalen of Christiania. These superficially resemble the long curved forceps, differing in the shape of the blade. The advantages claimed are that they are easier to apply in high forceps deliveries and can always be applied to the biparietal diameter. In the maternity clinic in Vienna, the axis traction forceps have been abandoned in favour of this type for the past 12 months.

---

* The tour of which the above impressions are recorded was arranged by the National Union of Students of Great Britain. This body exists to represent English and Welsh students both nationally and internationally, Scotland having a union of its own on similar lines, and is a member of the Confederation Internationale des Etudiants (C.I.E.) to which the national unions of some 20 European countries are affiliated. The C.I.E. is concerned with the interests of university students the world over, and through it the unions of the different countries are brought into permanent contact. This facilitates the work of arranging a welcome for students going to study at foreign universities, as well as holiday tours, correspondence exchanges, &c. As an example of what is done the English National Union has this year arranged—in addition to the medical tour of Europe described above—tours of agricultural students to Denmark, of engineering students to Czecho-Slovakia, and general holiday visits to France, Belgium, Germany and Hungary. In every case the English party, which contained both men and women students, has been conducted and entirely looked after by students of the country visited. This has not only enabled them to meet and get to know foreign students, but has resulted in making the tours very cheap. Results have been uniformly successful.

Hydrotherapy and Heliotherapy in Vienna.

We visited the institute for Continuous Hydrotherapy. This form of treatment is employed in all cases of generalised dermatitis, especially salvarsan dermatitis, for neurological cases with bed sores and contractures, septic cases—e.g., ungating carcinoma of the rectum and appendix abscess. One of this last type of case had been in the bath continuously or 18 months. In the same building we saw the Wagner-Jauregg malaria-salvarsan treatment for syphilis.

Heliotherapy for pulmonary tuberculosis in children was seen in the department of pediatrics. The main roof of the building is asphalted, and a wooden roof about 6 feet wide placed round two sides. Under this roof are the cots. The children are kept out throughout the year, although in Vienna there may be 20 degrees of frost in winter.

The radiographic installations in all the places visited were of the most modern type, especially those of Zurich. n taking a radiogram, instead of conforming the tube to he patient as is usual elsewhere, the patient is here con-ormed to the tube. This is effected by means of an apparatus similar in principle to the operating table, the head, limbs, &c., being capable of being elevated or lowered.

We were interested to note the wider employment on the continent of local anæsthesia in surgery than is customary n Britain. General anæsthetics are administered by the "closed" method by means of elaborate instruments.

Paris was visited on our return journey, but we were unable to take the fullest advantage of the opportunities offered us there. Time pressed, and, moreover, our powers of observation had become somewhat exhausted, as our our had proved a strenuous though thoroughly enjoyable ne.

Methods of Teaching.

With regard to methods of teaching in medicine, we noticed one important difference between Central Europe n the one hand and France and Britain on the other. In German-speaking countries and in Holland much stress is aid on the laboratory, while in France, as in England, greater attention is paid to the clinical aspects of medicine. To the visitor it is the well-equipped and organised labora-ories which appeal most strikingly. Where the system of eaching is largely clinical, there is little to impress the eye, nd on a hurried visit it is impossible to form a correct stimate of its scope. The value of each method of teaching an only be proved by ultimate results, nor is this the ccasion to discuss that side of the subject. The question f language is one which need not deter the intending student from Britain. Cliniques and lectures are given in English in many of the schools, and particularly in Vienna, where there are at present many Americans, is English argely used. There is an arrangement between some of he American and continental universities whereby assistants re exchanged for periods of 12 months. We met some of hese American assistants in Zurich and Paris.

The chief value of such a tour for medical students lies n the appreciation gained of a wider medical horizon than an be seen from the viewpoint of one particular school. t is of especial service to the senior student or newly qualified man in showing where and on what lines he might pursue is post-graduate studies.

PUBLIC HEALTH IN BIHAR AND ORISSA.[1]

ACCORDING to the census of 1921 the population of this rovince was found to be 34,002,189, not including the tributary States of Orissa, in which vital occurrences are not recorded. The birth-rate was 34·6 per 1000, as compared with 32·2 in 1920, and 30·4 in 1919, showing a further recovery from the conditions prevailing in 1918–20, that were due to the epidemic of influenza, high prices, and food carcity; though considerably below the decennial average f 39·2. In the several districts the ratio varied from 6·9 in Purnea and in Singhbhum to 40·2 in Angul and 40·7 n Monghyr. In the rural areas the ratio was 34·8, ranging rom 26·8 in Darbhanga and 26·9 in Singhbhum to 40·2 in ngul and 40·8 in Monghyr; and in the towns 29·3, ranging rom 13·6 in Balasore and in Dhanbad, to 41·3 in Jamalpur, 2·1 in Hajipur, and 45·3 in Sahibganj. The general death-rate was 32·8, as compared with 30·9 in 1920, 40·0 in 1919, nd 35·6, the decennial average. In the districts of Gaya nd Shahabad the ratios were 53·5 and 53·4 respectively, n Darbhanga and in Santal Parganas 23·7, and in Purnea nly 21·6. In the towns the variations were extreme: at alganj the mortality was 64·7, at Katihar 7·2 per 1000. The infantile mortality, 159·0 per 1000 births, was some mprovement on the corresponding rate (169·5) in 1920. The general death-rate among Hindus, who form the bulk of the population (28,161,118) was 33·5; among Mohammedans 28·0, and among Christians 19·7 per 1000.

Cholera showed a considerable increase from 0·7 deaths per 1000 in 1920 to 2·6 in 1921, this figure being also the average for the decennium (1911–20). In one district only (Angul, population 182,574) was there no death from this cause. The incidence was highest in Gaya rural district, where there were 27,119 fatal cases (13·0 per 1000), the adjoining Patna district, with 17,810 deaths (12·9) being similarly affected. Lieut.-Colonel W. C. Ross, I.M.S., Director of Public Health, who submits this report, is "strongly of opinion that the epidemic prevalence of cholera is largely associated with the prevalence of flies, and that good conservancy and the rapid removal of excreta (in which flies lay their eggs and breed) are fully as important measures for the prevention of cholera as the provision of pure water-supplies, and that both these preventive measures should be widely adopted if cholera is to be prevented as an epidemic disease." Such measures must be decentralised and carried out locally by the district boards and municipalities. The conditions most favourable for fly-breeding appear to be a mean temperature of about 85° and a humidity over 70 per cent. Heavy rainfall saved the situation early in August, and cholera immediately began to abate. The total cholera deaths amounted to 90,688, of which 26,710 occurred in July and 38,568 in August; in September they fell to 6724. Small-pox showed considerable improvement, 0·2 deaths per 1000, compared with 0·6 in 1920; in Palamau district the mortality was 0·9, and in Patna 0·8; in Angul district there was not a single death from this disease. The report states that "vaccination is the best, and the only real, means of prevention of small-pox; there is no doubt but that the cost of vaccination work is a splendid and profitable investment of public funds. . . . It would therefore appear to be wise and proper to organise the work more effectively, and to make vaccination compulsory and free, in order to get the whole population protected, and thus abolish a disease which is, of all diseases, the most easily and cheaply preventable." This is without doubt the proper course to pursue, and it is to be hoped that the executive authorities will support the Director of Public Health in the manner indicated.

The fever statistics (22·6 deaths per 1000, compared with 22·0 in 1920, and a decennial average of 23·3) varied in the rural districts from a mortality of 12·0 in Puri to 37·5 in Shahabad; and in the towns from 5·5 in Katihar to 30·7 in Gaya. During 1920 and 1921, 83,266 children were examined for enlarged spleen; the percentage found was 11·58. In the three districts of Muzaffarpur, Darbhanga, and Monghyr the ratios were found to be 0·56, 0·56, and 0·50 respectively, while in Singhbhum, Angul, and Balasore the ratios were 56·62, 65·55, and 68·29. "The prevention of malaria and hookworm constitutes the most important, and at the same time the most difficult, problem in the public health administration of the province." Colonel Ross considers that it is not practicable to prevent malaria, or reduce it permanently or on a large scale, by quinine; non-productive operations, such as draining, levelling, oiling of water surfaces, &c., are not feasible on a large scale over an enormous area. "What is wanted is a policy of malarial prevention which will pay its own way. . . . Such a policy is being carried out in Italy and Spain; it consists in combining agricultural improvement with sanitation, by draining or flooding marshes and wet lands in a scientific manner, so as to produce larger crops, and at the same time reduce the breeding of mosquitos." The Government of Bengal is now moving in this direction, and a similar action is suggested in Bihar and Orissa. The expense, of course, would be great, but the return would undoubtedly be remunerative.

The plague death-rate was 0·4 per 1000, compared with 0·5 in 1920 and 1·2 the decennial average. The districts of Patna (1·6 deaths per 1000), Saran (1·3), and Darbhanga (1·1) were most affected; Orissa division was entirely free. The towns, with a mortality ratio of 1·5 per 1000, suffered more than the rural districts (0·4). "The only preventive measure of real practical value is evacuation, which is now carried out by the people themselves in the majority of places." But "the better and permanent way would be to make the houses so that the rats were compelled to leave." With regard to respiratory diseases, from which the mortality was 0·2 per 1000, the same as in the preceding year, and in the decennium, it is stated that the toxin of influenza precipitates an attack of acute malaria in the many patients who harbour the malarial parasite, leading to a complicating pneumonia, which often proves fatal; quinine should therefore be given to prevent this complication. Dysentery and diarrhœa caused a death-rate of 0·8 in the rural districts and 1·6 in the towns; in the former, Puri and Cuttack districts suffered most with ratios of 5·3 and 5·0 respectively; in the towns, Puri (8·5), Jajpur (5·8), and Sambalpur (5·8). This prevalence is attributed chiefly to the bad state of the water-supply in Orissa division. In regard to hookworm disease (from which it has been found that approximately two-thirds of the population of Bengal are suffering, as well as large numbers in the districts of the United Provinces adjoining Bihar), investigations have been carried out at the Patna Lunatic Asylum, in several jails, and on a large scale among the mining population of Jharia ; from 50 to over 70 per cent. of those examined have been found to be affected. Local conditions of overcrowding and general filth, as happens in the temporary collection of large numbers of coolies in construction works, lead to the spread of the disease. Its prevention "is very largely an economic question, and, unless it is considered and attacked from that point of view, little or nothing can be done to deal with it." In a subsequent section of the report (para. 54) Colonel Ross emphasises the point that "Public Health is purchaseable, and the people will only obtain the quantity and quality for which they are prepared to pay. . . . In other words, public health is fundamentally an economic question." The three essential factors are economic progress, education of the people, and legislation. "The greatest is the need for economic progress. . . . The wherewithal must be provided, otherwise the work cannot be done." This may be admitted ; but, on the other hand, it must also be acknowledged that a population living under insanitary conditions cannot be healthy, and therefore cannot perform the work, or produce the results that would be obtained by a similar population living under healthy conditions ; and it has been established over and over again that expenditure on sanitary works, properly carried out, justifies itself in the most decisive manner, and to the fullest extent.

---

(*To be continued.*)

THE NATURE AND USE OF THE AIR.

Few stories in the history of science are more romantic than that of the discovery of the nature and use of the air. Its importance to chemistry, physics, and physiology is inestimable, and it is pleasing to think that several of our own countrymen have taken a conspicuous place in this important phase of the history of science. The modesty of Boyle, the genius of Mayow, the careful thoroughness of Black and Hales, and the patience of Priestley, misguided phlogistonian though he was, are lessons not easily forgotten. Miss C. M. Taylor has well summarised the subject in a little book entitled "The Discovery of the Nature of the Air, and of Its Changes during Breathing" (London: G. Bell and Sons, Ltd. 1923. Pp. 84. 1*s.* 6*d.*), a really excellent little volume which should have an instant success.

POLISHED RICE AND BERI-BERI.

Dr. F. E. Wood, in the medical report (1922) of the Federated Malay States, makes some interesting observations on the effects of increased consumption of polished rice among the Chinese and Malay population. It appears that since polished rice is now more easily obtainable than it was two or three years ago, the Chinese are reverting to it in preference to undermilled rice. The Malay natives are following their example, since the polished rice is both cheaper and more attractive than the more wholesome variety. As a result, beri-beri has greatly increased in the last two years. During the war the incidence of beri-beri was particularly low as, Dr. Wood states, owing to the shortage and control of rice, the Chinese were driven to employ other foodstuffs. Steps are being taken to warn the people of the dangers of polished rice as compared with undermilled or parboiled rice. Extract of rice polishings made by the Institute for Medical Research at Kuala Lumpur is now freely used in the treatment of beri-beri cases. It is especially useful in acute cases and undoubtedly tends to shorten the course of the disease.

VACCINATION IN THE N.W.F. PROVINCE, INDIA.

Lieut.-Col. W. M. Anderson, Director of Public Health in the North-Western Frontier Province, in his report for the year 1922–23, comments on the satisfactory increase in the number of vaccinations. The total number of operations (vaccinations and re-vaccinations) performed in the settled districts and agencies during the year amounted to 144,155, compared with 100,219 in 1921–22, thus showing an increase of 43,936 ; of this total 11,505 appear to have been unsuccessful. The successful primary vaccinations were at the rate of 40·31 per mille, the average for the preceding four years being 36·98. This is also a great improvement in the numbers of re-vaccinations. The incidence of small-pox has fallen concurrently ; during the past quinquennium the average annual number of deaths was 805 and the mortality per 1000 of the population was 0·37. During the year under report there were 118 deaths from small-pox, giving a ratio of 0·05 per 1000 of population. Colonel Anderson states that vaccination is gradually becoming more popular among the rural population and resistance to primary vaccination is not offered. The glycerinated chloroform lymph used was procured from the Punjab Vaccine Institute throughout the year.

A HYGIENIC BREAST-PUMP.

We have received a specimen of the Aspirateur Tourtier (9, rue du Regard, Paris), which is a breast-pump made entirely of glass and rubber, easy to manipulate and sterilise. Suction is produced by simple withdrawal of a piston, and the pressure can be released at any moment by removing an indiarubber stopper. The invention, it is stated, has been adopted at a number of the principal maternities in Paris, and it may be of service in the case of weaklings where neither mother nor nurse can carry out the hand-expression which is the usual practice in this country. It may also prove of use for women who are obliged to go out to work and for the purpose of obtaining breast milk from a wet-nurse for other babies, as is now practised widely in America and has recently been tried with success at the Manchester Children's Hospital. The price of the apparatus is given as 10*s.*, and it can be obtained in this country through the Sole Agent, Tourtiers Aspirators, 70, Victoria-street, London, S.W.1.

LONDON DOCTORS AND DENTAL SURGEONS, 1923–24.

This new directory, by reason of its size, its red cover and its style of printing calls to mind the Dentists' Register issued under the direction of the Dental Board. It is, however, a complete list of legally qualified (registered) physicians and surgeons and of graduates and licentiates in dental surgery, practising in Greater London, including Bromley, Croydon, Ilford, Kingston, Richmond, Surbiton, and Woodford. The General Medical Council has officially advised the publishers that this work conforms to its requirements, and the directory actually includes all additions to the Medical and Dental Registers up to May 31st last. The information given in the 300 pages is allocated under the following five headings: (1) Name, chief professional qualifications, and date of registration (with partnerships, if any) ; (2) addresses, telephone numbers, consulting and visiting hours ; (3) description of practice ; (4) nature of work ; (5) chief hospital or public medical appointment, (*a*) present, (*b*) late. The matter is neatly and attractively set out and we have noticed few errors for a new work of this scope. The name, however, of one well-known surgeon lacks a vowel. An avowed purpose of the volume is to bring the profession and public into closer contact, and while being of service to the practitioner at the same time to render the profession more accessible to the laity who, without being confused by a burden of detail, may rapidly find the data they seek. The Grafton Publishing Co. (Chichester House, Chancery-lane, W.C. 2) proposes to issue the directory annually. The price is 15*s.* 6*d.*

Messrs. W. and G. Foyle, Ltd. (booksellers, 121-125, Charing Cross-road, London, W.C.) have sent us a new catalogue of Department No. 9, containing recent and secondhand books on medicine, surgery, nursing, and pharmacy. The list is classified into general and special subjects and contains books both new and old, some of the latter now being not readily obtainable. The list should prove useful to that large circle of medical students who would like to read more than they can afford to buy at published prices.

W. J. H. D.—There are several institutes interested in any new suggestions for the treatment for cancer—e.g., the Cancer Hospital (Free), Fulham-road, London, S.W. 3, the Middlesex Hospital (Cancer Research Laboratories), London, W. 1, the Imperial Cancer Research Fund, 8–11, Queen-square, Bloomsbury, London, W.C. 1. The remarkable find might be submitted to one or other of these.

Messrs. Baillière, Tindall and Cox (8, Henrietta-street, London, W.C.) have issued a list of Works on Dentistry, published and sold by them, containing the names of more than 100 books and journals classified under subject headings. In each case the date of publication is given.

Corrigendum.—Dr. H. B. McCaskie informs us that the remarks on antenatal precepts attributed to him in our report of the Section of Obstetrics, B.M.A. (The Lancet, Sept. 15th, p. 562) were not made by him. He holds exactly opposite views on the subject of antenatal examination.

The Effect
OF
X RAYS OF DIFFERENT WAVE-LENGTHS UPON SOME ANIMAL TISSUES.

PROOF OF DIFFERENTIAL ACTION.[*]

BY S. RUSS, D.SC., F.INST.P.,
JOEL PROFESSOR OF PHYSICS IN THE UNIVERSITY OF LONDON.

(From the Cancer Research Laboratories, Middlesex Hospital.)

IN a paper[1] upon the germicidal action of ultra-violet rays, it is shown that a marked differential action exists in this part of the spectrum—i.e., electromagnetic disturbances have a different effect upon the same kind of organism according to the wave-length operating. It was found that when micro-organisms were exposed to the ultra-violet and visible radiation from a tungsten arc for a considerable period of time germicidal action stopped abruptly at $\lambda = 2960$ Å.U. It was possible in this particular instance to correlate the differential action with a selective absorption by the micro-organisms of just those wave-lengths which had germicidal action upon them.

In attempting to extend this kind of experiment into the region of X rays it soon becomes certain from ordinary electroscopic absorption measurements that this correlation, even if it exists, will not be found, because the absorptive power exhibited by a medium upon a beam of X rays is dependent in so many cases solely upon the mean density of that medium. Hence, if we take a section of some animal tissue the density of which is about the same as water, the absorption which it will exert upon a beam of X rays will be practically the same as that of a layer of water of equal thickness, in spite of the fact that in the layer of tissue the composition varies from point to point according to the cellular structure involved. In order to reveal this point-to-point absorption it would be necessary to construct electroscopic instruments on a microscopic scale.

In view of these difficulties, it was decided to select X rays of a certain restricted range of wave-length, and, in the first place, to expose tissues to measured doses of this radiation. The next step was to go considerably higher in the scale of wave-length, arrange that exactly the same dose of radiation was given, and see whether the same effects were produced. If different, then it would be proved that a differential effect exists; and these experiments support this view. The proviso is inserted here that this differential effect may really be due to a selective absorption of the radiation by some constituent part of the cells, which cannot, of course, be detected by the usual absorption measurements. These experiments have been carried out on the normal skin of the rat and Jensen's rat sarcoma, which, when inoculated subcutaneously, grows progressively in a large percentage of cases. It has been shown in previous papers that the rate of growth of these tumours can be slowed up or completely stopped by accurately adjusting the dose of radiation; if growth is permanently stopped we say that a lethal dose has been given.

In view of the fact that proof of a differential action will depend almost entirely upon the reliability of the physical methods used for measuring the radiation, the subject matter of this paper is divided into two sections, the first of which is devoted to certain physical considerations.

PHYSICAL SECTION.

Ranges of Radiation Used.—The ranges of X ray wave-lengths used have been chosen so that it may be possible to draw conclusions from the observations which will be applicable to radiotherapy. One group of wave-lengths used was that which was emitted by an X ray tube running at an alternative spark-gap of 4 cm. between spheres 5 cm. in diameter; the wave-lengths would range for the most part from about 0·45 to 0·30 Å.U., and reference will be made to them in the text as "soft" X rays. The other group chosen was a comparatively small group of wave-lengths obtained by running the X ray tube at an alternative spark-gap of 10 cm. between the spheres and screening the radiation by 1 cm. of aluminium. Under these conditions the transmitted rays are not far from being homogeneous, with a wave-length of 0·168 Å.U.; reference will be made to them as "hard" X rays. The figures relating to wave-lengths are derived from aluminium absorption measurements.

Definition of the Dose of Radiation.—In this paper it has been decided to take the dose to be measured by the amount of radiation absorbed by the tissue, and it will be referred to in the animal experiments section as the absorption dose. This is different from the usual practice, which is to take the dose as measured by the product of incident intensity and time, where the incident intensity I is the amount of energy incident per second per unit area. The absorbed radiation $A = I\ (1 - e^{-\mu x})$, where μ is the coefficient of absorption and x the thickness of tissue. When the wave-length is changed the value of μ is in general different, so that A and I are not in a constant ratio to one another for different kinds of radiation. In a similar way an electroscope does not measure the energy incident upon it, but only that which is absorbed in it and used to produce ionisation. We can represent this fraction approximately by $A_0 = I\ (1 - e^{-\mu_0 x_0})$. It is the quantity A_0 which is measured by the reading of the instrument. If we assume that A_0 bears a simple proportion to the energy absorbed by the tissue (A), and that this ratio is the same for both "hard" and "soft" rays, then the readings on the electroscope multiplied into the time measure the dose.

Experimental Method of Measuring the Dose.—In applying the method outlined we have to design the electroscope so that the above assumptions shall be most nearly satisfied. It is well known that when a beam of X rays meets an obstacle secondary radiation originates, and the general character of this radiation changes as the incident wave-length is varied. The resulting ionisation in, say, an air space depends upon the general character of the radiation traversing it, so it is clear that the simpler we are able to keep the conditions the more likely we are to avoid the various complications of secondary radiation. For this reason a short air path is used as our standard ionisation chamber, and it is arranged so that in the passage of the beams of X rays through this air path no solid surfaces are struck. In this way secondary and scattered radiation effects are reduced to a minimum, and we can then assume that when an equal ionisation is produced by two beams of different wave-lengths there is an equal expenditure of energy producing such ionisation in the two cases.

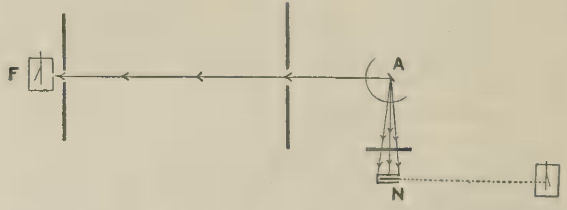
The experimental method of measuring the dose of radiation may be seen from Fig. 1. X rays originating at A go along the paths indicated, the vertical beam to an ionisation chamber N connected to an electroscope, which will be called the near electroscope; the horizontal beam to an ordinary gold-leaf electroscope situated in a room about 4 metres away; this will be called the far electroscope. N could be swung in and out of position, and this position, when it was receiving the vertical beam, was that occupied by the experimental material; in this way a measure was always obtained of the radiation to be used, simultaneous measurements being taken at F. When the actual exposure of the tissues took place, N had to be swung out of position, but as there had previously been simultaneous readings on F and N, it was not a difficult matter to ensure that the radiation was of the character and intensity required, for during the exposure, which in some cases lasted over an hour, observations of the intensity at F were made every minute; in this way an invaluable check upon the constancy of the radiation was obtained, and any variations in it were made good by a slight lengthening or shortening of the exposure. F and N were standardised before use on all occasions by means of a known quantity of radium.

---

[*] This paper appears in the Proceedings of the Royal Society, B. vol., p. 95, and is here reproduced by permission.

[1] Browning and Russ: Proc. Roy. Soc., B. vol., p. 90 (1917).

Fig. 1.



Effect of Variations in the Ionisation Chamber.—It has already been mentioned that the form of ionisation chamber at N, which we look upon as the standard, consisted of a simple air path. This was obtained by taking a lead cylinder and cutting a small hole in it transversely to its length. Two electrodes were set up vertically within the cylinder, so that the beam of X rays came down between them but without touching them; one was connected by means of a wire to a gold-leaf electroscope about 6 feet away; the other terminal was earthed. The saturation current obtained when X rays of a certain wave-length traversed the air gap was taken to be proportional to the quantity of radiation absorbed. The actual reading when multiplied by the time of exposure constitutes a measure of the dose. When used for measuring X rays of a different wave-length the output can be adjusted to give the same reading on the electroscope, and so equal doses can be given.

The ionisation curves obtained with this air chamber for the two regions of wave-length under investigation are practically identical; see Fig. 2, in which the crosses correspond to "hard" rays and the circles to "soft" rays. This is a graph of a number of simultaneous observations on the near and far electroscopes; by using a diaphragm in front of F it was possible to get identical readings on F with "hard" and "soft," when these beams were giving identical readings on N.

Various ionisation chambers were used and the effect of varying the ionisation chamber at N is shown in Fig. 3. These three graphs were obtained in the manner just described; the ionisation chamber in (*b*) was a shallow wooden box with a central electrode of wood, in (*c*) it was the same box, but the central electrode was of aluminium, and in (*d*) it was a shallow aluminium box with an electrode of the same metal. The graphs show that when equal readings are obtained on the near electroscope, the readings of the far one are higher when dealing with "hard" than with "soft" rays, except when the air ionisation chamber is used.

Table I.

Ionisation chamber used at N.	Ratios of readings of far and near electroscopes for different rays when near electroscope gives uniform readings.
(*a*) Air ionisation chamber only ..	1·0
(*b*) Wood ionisation chamber: wood electrode	1·37
(*c*) Wood ionisation chamber: aluminium electrode	1·73
(*d*) Aluminium ionisation chamber: aluminium electrode	2·03
(*e*) Paper ionisation chamber: aluminium electrode	2·52

Table I. shows the extent to which this is the case. It follows that when we use, say, chamber (*d*), and adjust the readings of N to equality for "hard" and "soft" rays, we are really supplying in equal times doses for "hard" rays 2·03 times as great as for "soft" rays. It might be possible by using a measurin instrument which, owing to secondary radiatio phenomena, specially favours "soft" X rays, that th existence of a differential effect upon animal tissue could be entirely masked. It is not unlikely tha these phenomena have played some part in th observations of Friedrichs,[2] from which he ha concluded that no differential effect upon tissues exist

In view of the fact that the constructional feature of the ionisation chamber may account for suc important differences as appear in Table I. detail are given below of the dimensions of (*a*), (*b*), (*c*), &c They are as follows:—

(*a*) Air gap only—dimensions of gap about 1 × 0·4 × 2 cms

(*b*) Rectangular parallelepiped of wood, external dimension 3·4 cms. long, 1·5 cms. wide, and 0·4 cms. deep, thickness o wood 0·3 mm.

(*c*) Same as (*b*), but electrode of aluminium 0·2 mm. thick.

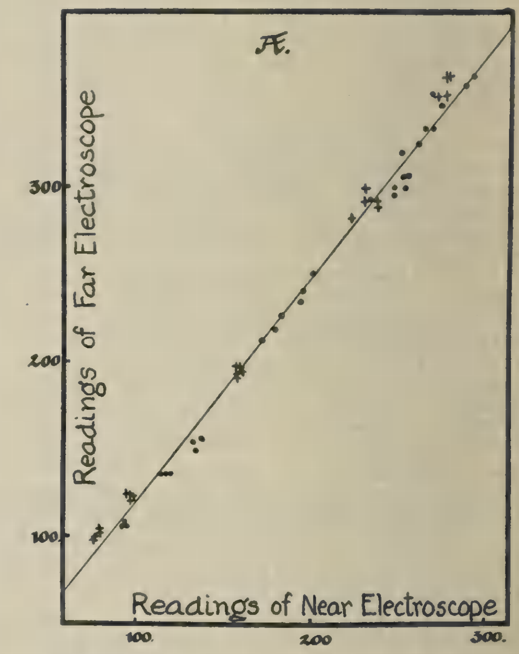
(*d*) Same dimensions as (*b*), but all of aluminium 0·3 mm thick.

(*e*) Cylinder of thin paper about 0·8 mm. thick, length 3· cms., diameter 1·5 cms., central electrode an aluminium wire.

ANIMAL EXPERIMENTS SECTION.

Experiments upon Tumours.—For the tumou experiments the method of exposure was that adopte by Wedd and Russ.[3] A thin slice of tumour abou 1–2 mm. thick is placed between thin sterile mic sheets and exposed to the radiation for the lengt of time desired; small pieces of the tumour are the inoculated into normal rats and the subsequen growth determined by frequent caliper measurements Here again the animal variation has been eliminate as far as possible in the following way. The experimental batches of animals inoculated numbered abou 20, and each rat was usually inoculated with three small pieces of tumour; one had been exposed to "hard" rays, one to "soft," and the control had had no radiation at all.

Fig. 2.



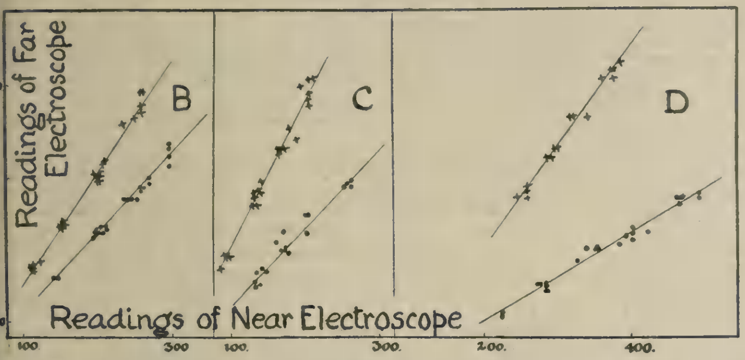
The first step was to find the dose of "soft" X rays which was just sufficient to produce a lethal effect upon the tumour; this gave a certain rate upon the Standard electroscope at N (Fig. 1), and this rate could be accurately duplicated with "hard" X rays, and the corresponding dose of these rays could be given to the tumour. Two pieces cut from the same tumour were exposed, one to an absorptio ose, which was practically a lethal dose, of " soft " rays (exposure 53 minutes), and the other to an qual absorption dose of " hard " X rays (exposure so 53 minutes). Small portions of the irradiated imour were then inoculated into the right and left xillæ of 20 rats and non-irradiated tumour in the ght groin. The Chart (Fig. 4) shows the result ıree weeks later, from which it will be seen that though the absorption dose of " soft " X rays was thal to the tumour, an equal absorption dose of hard " X rays resulted in a very considerable degree growth. The tumours are drawn to full-scale.

---

[2] Friedrichs: Physikalische und biologische Grundlagen der Strahlentherapie (1918).

[3] Wedd and Russ: Jour. Pathology and Bacteriology, vol. xvii., p. 1 (1912–13).

FIG. 3.



In the next series of experiments upon the tumour ells it was arranged to find out how much greater ı absorbed dose of " hard " X rays it was necessary give in order to get the same effect as with " soft " ys; the effect sought was a lethal effect upon the ımour. The results in Table II. were obtained under ıese conditions. For any particular time of exposure ıe absorbed dose of " hard " rays was 2·53 *times* as eat as that of the absorbed dose of " soft " rays; spite of this increase in the amount of X ray ıergy absorbed it will be seen that the lethal fect was reached a little sooner with the softer ıdiation, so that this number would not appear to quite large enough as a measure of the differential tion.

Another experimental series undertaken, so that ıe absorbed dose of " hard " rays was 2·74 times as eat as that of the " soft " rays, showed that in this ıse the lethal effect was obtained a little *sooner* ith the " hard " than with the " soft " rays. Two ırther series on the same lines showed that the lethal fect upon the tumour was obtained with " hard " ıd " soft " rays when the absorbed dose of " hard " ys was in one case 2·85 and in the other 2·42 times large as the absorbed dose of " soft " rays.

TABLE II.

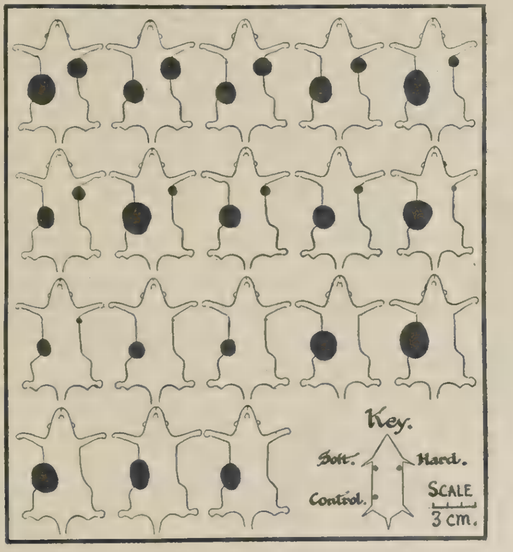
umber of nimals.	Number of control inoculations which grew tumours.	Time in minutes of exposure of the tumour.	Tumour inoculations which grew after exposure to—	
			" Soft " X rays.	" Hard " X rays.
12	9	39	3	9
22	18	50	4	11
12	11	56	1	4
12	8	61	0	1

If we take the whole series into consideration, volving experiments and observations upon about)0 rats, it appears that when a quantity of energy expended in a layer of tumour by a beam of what here termed " soft " X rays, then in order to get ıe same degree of action upon the tumour (namely, revention of growth) with a beam of what is here rmed " hard " X rays, it is necessary to arrange ıat about 2·6 *times* (average of the numbers in the xt) as much energy is expended. This number ay therefore be looked upon as a numerical measure of the degree of the differential action, and might be termed the " therapeutic factor."

Skin Experiments.—In the experiments upon the normal skin the rats were given urethane and exposed to a beam of X rays projected vertically downwards. A lead screen with a square aperture was placed over the animal to localise the exposure. The screen was first placed in such a way that the aperture came between the shoulders of the animal and a dose of " soft " X rays given to this area; the screen was then moved so that the aperture came low down in the mid-line and a measured dose of " hard " X rays given to this area. By exposing two areas of the skin of the same rat, comparisons between the effects of " hard " and " soft " X rays were made more accurate. The rats were generally irradiated in pairs and in order to exclude " local " variations the upper area of one rat and lower area of the other were exposed to the same wave-lengths.

When an animal is irradiated in this way, the radiation which is scattered back from the body of the animal as the primary beam makes its way through it, contributes something to the dose absorbed by the skin. In order to allow for this fraction, when the dose of radiation was measured, a rat was placed just beneath the electroscope so that the back radiation could contribute to the ionisation produced by the direct beam. A difference could be measured with the animal in or out of position, but it only amounted to a few per cent. of the total ionisation. After the X ray exposure, a careful scrutiny was kept of the successive changes in the skin. In some cases the exposures were long enough to produce ulcers which eventually healed; with shorter exposures, the irradiated region was not damaged enough to prevent the re-growth of hair, though in most of these cases there was a loss of pigment.

FIG. 4.



A preliminary series of experiments upon 18 rats on the lines indicated served to show that in order to get the same degree of reaction in the skin it was necessary to give a considerably greater absorbed dose of " hard " than " soft " X rays. The extent of this differential action was more accurately gauged from some further results obtained after the exposure of another series of 48 rats to measured doses of the two types of radiation.

Detailed records were kept of the times at which the various reactions occurred, and in many cases the observations were continued over a period of nearly a year.

* Figures in brackets denote number of rats.
† Nearly complete. ‡ Very slight. ‖ Other very slight.

The times of exposure to the "soft" rays ranged from 21–50 minutes and to the "hard" rays from 30–150 minutes, and it was found that a practically identical degree of reaction was obtained in the skin of the rats when the absorbed dose of "hard" X rays was six times that of the "soft"; this number may therefore be taken as a measure of the differential action of the two sets of wave-lengths. If we use the term "therapeutic factor" it is seen that a considerable difference is found for skin and for tumour. In several cases where the general degree of reaction of the skin to "hard" and "soft" rays was about the same (produced, however, by widely different doses) there still seemed some small difference in the nature of the reaction. With the "hard" X rays the onset of the reaction was slower, and the condition of the hair many months later was nearer the normal.

DISCUSSION OF RESULTS.

If the method by which comparison is made of the amounts of energy liberated in the tissues by the two beams of X rays under consideration is a valid one, then the results show that when equal amounts of X ray energy are absorbed from beams of different wave-lengths by animal tissues, the reactions of these tissues may differ considerably in degree and possibly to some extent in nature.

The conclusions reached have some bearing in radiotherapy. The experiments show that a bigger differential effect between "hard" and "soft" X rays exists for the skin of the rat than for the tumour cells. Provided this also holds for the human subject it is one argument for the use of very hard X rays or γ rays when tumours at a considerable depth below the skin have to be irradiated. The conclusion would perhaps be just the reverse in superficial conditions not involving the irradiation of normal skin.

The result also raises the question whether the specification which has been adopted by Seitz and Wintz [4] for expressing the carcinoma dose in terms of the skin dose is sufficiently rigorous, for this may be a function of the wave-length.

The two main results obtained are that about six times as much short wave-length energy as long wave-length energy must be expended in a layer of skin in order to produce equal reactions and that this factor falls to about 2·6 in the case of the tumour. We may question whether these are not cases in whic the molecular configuration, apart from the atomi is more affected by electrons of low than of hig velocity. The experiments of C. T. R. Wilson [5] hav produced direct evidence of the part which th electrons liberated in the track of a beam of X ray play in ionisation, and it would not be irrational t suppose that the slower electrons which would b released by the longer wave-length can give rise t more pronounced effects in the tissues than th quicker ones liberated by the shorter wave-length even though a similar expenditure of energy occu in the two cases.

TRAUMATIC INTESTINAL RUPTURE.

BY GRANT MASSIE, M.B., B.S. LOND.,
F.R.C.S. ENG.,
SURGICAL REGISTRAR, GUY'S HOSPITAL.

INTESTINAL rupture, without penetration of th abdominal wall, sometimes referred to as subcutaneou rupture, is not an accident of common occurrence The 34 cases upon which this report is based wer collected from the records of Guy's Hospital betwee the years 1899 and 1923, a comparatively long period

Situation of Rupture.

Stomach	4	
Duodenum	3	
Duodeno-jejunal junction	1	26
Jejunum	14	
Ileum	8	
"Small intestine"	3	
Cæcum	1	

The majority of ruptures clearly occur in the smal intestine, and the comparative immunity of th stomach, the duodenum, and the colon is striking Regarding rupture of the small intestine, the jejunum was more commonly injured than the ileum, and o the 14 jejunal lesions 7 were found within 18 inche of the duodeno-jejunal junction, an occurrence whic cannot be entirely explained by chance. Othe writers have found that whereas the jejunum i commonly injured in its first 3 feet, the ileum i commonly injured in its last 3 feet. Unfortunately of the ruptures of the ileum in this series the exac situation was only mentioned in three cases. In two of these it was 4 feet from the ileo-cæcal valve, and in the third 2 feet from the valve.

It is difficult to account for the frequency of lesions in the upper part of the jejunum without supposing that the small intestine, in its upper part at any rate bears some more or less constant relationship to the vertebral column, against which it is crushed by the force applied to the abdominal wall. Mall[1] has stated that the six primary loops of small intestine occupy definite positions within the abdomina cavity, while Grégoire[2] and many other anatomists believe that this is also true of the intestine in its final state of development. It is certainly very suggestive that it is the second or third loop of the jejunum which is commonly injured at the point at which it crosses the vertebral column.

Character of the Lesion.

Of the ruptures of the duodenum, two showed complete transverse division, and all were associated with other severe injuries in the upper abdomen. In the small intestine the majority of the lesions were partial ruptures—that is, the continuity of the bowel was not completely divided, although all its coats were involved. Of the nine cases of complete transverse division, seven were in the jejunum and two were in the ileum.

It is noteworthy that, whereas all the cases of rupture of the stomach and the duodenum were complicated by other injuries, usually intra-abdominal, those with rupture of the small intestine, with the exception of two, were uncomplicated by any such injury. The lesion was usually single. Five cases occurred in which there was a double lesion. In these the perforations were usually close together, although in one case they were separated by a distance of 5 feet. In many of the cases of multiple perforations of this kind already reported the patient has been kicked by a horse, and it has been suggested that these injuries were due to the impact of the two ends of the hoof. In only one of the five cases in this series was the injury due to a kick; in another the patient was crushed between the buffers of a train, and it is possible that the same explanation may also apply here.

The extent of the rupture is of great importance, and it is by no means impossible that small perforations should become sealed off by the adhesion of the great omentum, aided by the eversion of the mucosa so typical of intestinal rupture. The following case illustrates the possibility of this happening:—

CASE 26.—A man of 28 was struck in the abdomen by the open door of a goods van while working on the railway. On admission he complained of great abdominal pain, and the abdomen was both rigid and tender. His pulse was 66 and there was some vomiting, which continued until the following day, when it seems that his condition somewhat improved. Twelve days later he developed definite signs of intestinal obstruction and operation became necessary. On opening the abdomen it was found that the omentum had become adherent to the ileum at one point, thus forming a band which was the cause of the obstruction. The patient died, and at autopsy it was found that the bowel had been ruptured at the point at which the omentum had become attached. It is reasonable, therefore, to assume that similar cases occur in which perhaps the patients are more fortunate in escaping the dangers of intestinal obstruction. Without the complication recovery in this case might well have been complete.

Injury to the Mesentery.

The complication of injury to the mesentery is found, according to Moynihan,[3] in 10 per cent. of cases. In most cases it does not appear to influence the prognosis except when the mesentery is torn from the bowel along the line of its attachment. This condition, termed by Sencert[4] "mesenteric disinsertion," has received little attention from surgical writers hitherto, but it deserves notice, since it may profoundly modify both diagnosis and prognosis of the case in which it occurs. The following cases illustrate the possible results of this injury:—

CASE 12.—A man of 27 fell from a telegraph pole on which he was working a distance of about 50 feet. On admission the abdomen was rigid and his pulse was 96; liver dullness was normal. Within three hours there was marked pallor and the abdomen was greatly distended, suggesting the diagnosis of internal hæmorrhage. On laparotomy the jejunum was found disinserted for a distance of about 4 inches, and close to this was a small rupture of the bowel. "Several branches of the superior mesenteric artery were bleeding furiously."

CASE 31.—In this patient, a girl of 3, who had been run over by a light cart, internal hæmorrhage was not a feature of note. The patient complained of great pain and the pulse rose to 160. On laparotomy it was found that in addition to two ruptures, both of which were small, the bowel had become separated from its mesentery and was gangrenous. This necessitated resection, and the patient died.

The immediate consequence of mesenteric disinsertion therefore is hæmorrhage, which may in itself be sufficient to cause death; the more remote consequence is gangrene, which carries with it so high a mortality. Sencert,[4] in reviewing this aspect of intestinal rupture, was able to find only 30 recorded cases, but probably it is a complication far more common than these findings would suggest.

Nature of the Violence.

The cause of the injury was as follows:—

Run over	16	Kicked	2
Crushed	7	Knocked down	2
Struck by various objects	6	Fall	1

In the majority of cases the force applied was direct—that is, it compressed the anterior abdominal wall, crushing the bowel on the vertebral column. In two cases the force applied was indirect, and in each the patient was struck in the lumbar region, from where in some way the violence was transmitted to the abdominal contents. E. J. Senn[5] has reported and discussed two similar cases; in his own case a woman of 26 fell in the snow, striking her right buttock. Signs of peritonitis later appeared, and on opening the abdomen he found a small rupture of the ileum in the lower part of the pelvis. In the second case, reported by F. J. Bottomley,[5] the patient was struck beneath the angle of the left scapula and sustained a rupture of the duodeno-jejunal junction.

Cases 12 and 33 illustrate this peculiar type of injury. In the first, already referred to as showing the results of mesenteric disinsertion, the patient fell 50 feet, striking his right lumbar region and bruising the iliac crest. At operation a small perforation was found in the jejunum in addition to the injury to the mesentery, which has already been described. In the second case the patient was struck in the back by a railway engine. The lumbar muscles were severely contused, several of the lumbar spines were fractured, and there was also a fracture-dislocation of the third lumbar vertebra. It is indeed extraordinary that with such extreme violence the only resulting injury within the abdomen was a single rupture of the jejunum of no great size.

The mechanism of this type of injury is difficult to explain, and Senn came to the conclusion that it was due to "violent momentary vibrations in a coil of intestine overdistended with fluid contents." It seems that by this explanation Senn imagined that the affected coil was for the moment isolated from the segment above and below; if this is the case, however, it clearly cannot apply to the first of the above-mentioned patients, for no change affecting only the contents of a loop of intestine could possibly separate it from its mesentery. It seems more likely that trauma applied to the lumbar region causes a violent hyperextension of the lumbar column and consequently a tightening of the anterior abdominal wall. The bowel may well be crushed, therefore, in this type of injury, in exactly the same way as it is in the more usual case of direct violence.

It has already been pointed out that injury to the stomach and the duodenum was frequently associated with laceration of the liver, pancreas, or spleen, complications which patients with rupture of the small intestine usually escaped. The upper abdomen is relatively well protected by the downward projection of the thoracic wall, which covers it laterally and to a great extent in front. The contents of the pelvis are to some extent also protected by its bony walls, but not entirely so, since the pelvis is directed both upwards and forwards. It is clear, then, that the part of the abdomen most liable to injury is that which lies between these extremities; most writers on the subject agree that the dangerous area of the abdomen is that below the umbilicus, where the forward projection of the lumbo-sacral curve is most marked.

Signs and Symptoms.

In reviewing the signs and symptoms of intestinal rupture presented by the cases in this series it becomes evident that no one sign or symptom can be regarded as in any way diagnostic of the condition in its early stages. In nearly all the cases the predominating feature at the time of admission was pain, shock, or rigidity of the abdomen.

Pain.—This was very marked in most cases, and although sometimes localised was usually diffuse. Generally it appeared at the time of the injury, but in a few cases it was delayed. The pain usually increased in severity until operation was undertaken, although in one case it disappeared within a few hours of the injury. In this patient laparotomy was undertaken within seven hours of the injury, and death seems to have been due to shock.

Shock.—This was evident in the majority of cases, and was so marked in a few that it precluded operation.

TABLE I.—THIRTY-FOUR CASES OF TRAUMATIC INTESTINAL RUPTURE.

No.	Age and sex.	Dates of (*a*) accident, (*b*) admission, (*c*) discharge or death.	Nature of injury.	Symptoms and signs.	Treatment.	Result.	Condition found at operation or post mortem.
1	8 F	(*a*) 11/8/02 (*b*) 11/8/02 (*c*) 11/8/02	Run over by light van.	Abdomen rigid. Liver dullness absent. Right and left flank distended.	No operation.	D*	Rupture of stomach and upper pole of spleen. Peritonitis.
2	8 M	(*a*) 26/4/10 (*b*) 26/4/10 (*c*) 26/4/10	Run over by cart.	Abdomen rigid on left side. Pt. vomited blood. Pulse 120.	Laparotomy 17 hrs. after admission.	D	Rupture of stomach and pancreas. Large quantity of free blood in abdomen.
3	6 F	(*a*) 28/5/10 (*b*) 28/5/10 (*c*) 28/5/10	Run over by motor-car.	Abdomen rigid in epigastrium. Much pain and vomiting. Rigidity increased. Pulse rose to 120.	Laparotomy 2 hrs. after injury. Rupture sutured.	D	Rupture of stomach near cardia; 4 to 5 oz. of blood-stained fluid in abdomen.
4	7 M	(*a*) 28/6/20 (*b*) 28/6/20 (*c*) 2/7/20	Knock on back of head by motor-van.		No operation.	D	Fracture of base of skull. Rupture of lesser curvature of stomach.
5	5 M	(*a*) 24/12/02 (*b*) 24/12/02 (*c*) 24/12/02	Run over by hansom cab.	"Signs of abdominal injuries."	Operation refused.	D	Rupture of duodenum. Fracture of femur.
6	14 M	(*a*) 3/6/10 (*b*) 3/6/10 (*c*) 4/6/10	Run over by cart.	Much abdominal pain. Little bruising.	Laparotomy. Suture of duodenum.	D	Duodenum completely severed intraperitoneally. Fracture of spine.
7	5 M	(*a*) 28/9/22 (*c*) 28/9/22	Run over by light van.	Pt. greatly shocked. Band of bruising across epigastrium. Abdomen rigid and tender. Liver dullness at first normal, later diminished.	No operation.	D	Complete rupture of duodenum. Liver and spleen lacerated. Fracture of many ribs.
8	20 M	(*a*) 24/3/17 (*c*) 26/5/17	Crushed between pole of wagon and post.	Abdomen extremely rigid and distended; extreme pain; pulse 72; no bruising.	Laparotomy. Suture of rupture. No drainage.	R	Partial rupture at duodeno-jejunal junction.
9	9 M	(*a*) 6/2/02 (*b*) 6/2/02 (*c*) 7/2/02	Run over by van.	Much collapse; vomiting; pulse feeble.	Laparotomy. Suture of rupture.	D	Partial rupture of jejunum 13 in. from the duodeno-jejunal junction.
10	50 M	(*a*) 3/8/03 (*b*) 3/8/03 (*c*) 3/8/03	Playing with lad of 16, who accidentally sat on his abdomen.	No immediate pain. Later pt. vomited. Pulse 140. Dullness developed in left flank.	Operation refused.	D	Partial rupture of jejunum in two places, 4 ft. and 9 ft. from pylorus. Peritonitis.
11	33 M	(*a*) 13/9/05 (*c*) 14/9/05	Struck in abdomen by crane.	Much pain. Pulse 76, on following morning 108.	Laparotomy on following morning. Suture.	D	Partial rupture of jejunum just beyond its commencement. Laceration of pancreas.
12	27 M	(*a*) 29/9/05 (*b*) 29/9/05 (*c*) 30/9/05	Fall of 50 ft. from telegraph pole. Struck right lumbar region.	Abdomen rigid. Liver dullness normal. Pulse 96. Three hours later much distension and marked pallor. Bruise of right iliac crest.	Laparotomy 5 hrs. after admission. Suture and ligature of mesentery.	D	Partial rupture of jejunum. About 1 in. away mesentery of bowel completely separated from its attachment for 4 in. Several branches of sup. mesenteric artery bleeding furiously.
13	29 M	(*a*) 1/5/08 (*b*) 2/5/08 (*c*) 6/6/08	Kicked by horse.	Vomited at once and throughout the following night. Much pain. Rigidity.	Laparotomy. Suture, irrigation, No drainage.	R	Partial rupture of jejunum about 5 in. from duodeno-jejunal junction.
14	9 M	(*a*) 23/2/10 8 A.M. (*b*) 23/2/10 2 P.M. (*c*) 8/4/10	Crushed between two carts.	Abdomen rigid and tender. Pulse rose, 130.	Laparotomy 14½ hrs. after. Suture, drainage.	R	Partial rupture of jejunum about 18 inches from duodeno-jejunal junction.
15	21 M	(*a*) 30/12/15 9 P.M. (*b*) 31/12/15 5.30 P.M. (*c*) 5/2/16	Run into by barrow.	Walked to hospital. Slight bruise on abdomen which was tender and rigid. Pulse 132.	Laparotomy. Suture, drainage.	R	Partial rupture of the first part of jejunum. Much brownish fluid in abdomen.
16	30 M	(*a*) 25/5/99 (*b*) 25/5/99 (*c*) 27/7/99	Crushed between pole and wall.	Acute pain. Abdomen retracted and immobile.	Laparotomy 2¾ hrs. after injury. Anastomosis with Murphy's button.	R	Complete rupture of the jejunum.
17	50 M	(*a*) 22/5/01 (*b*) 22/5/01 (*c*) 23/5/01	Hit on abdomen by piece of marble weighing 15 cwt.	Extreme pain, which later disappeared. Much shock. Rigidity.	Laparotomy 7 hrs. after injury. Murphy button anastomosis.	D	,, ,,
18	47 M	(*a*) 29/6/04 (*b*) 29/6/04 (*c*) 30/6/04	Crushed between two barges.	Very collapsed. Much pain. Abdomen rigid. Left side dull. Pulse 100.	No operation.	D	Complete rupture of jejunum. Rupture of pancreas. Fat necrosis. Peritonitis.
19	18 F	(*a*) 6/5/08 (*b*) 6/5/08 (*c*) 7/5/08	Run over by heavy cart.	Much shock. Pulse 116. Swelling of left side of abdomen due to percussion.	Laparotomy. Murphy button anatomosis.	D	Complete rupture of jejunum near commencement. Much blood in abdomen.
20	23 F	(*a*) 26/8/12 (*b*) 26/8/12 (*c*) 27/8/12	Run over by motor-bus.	Much abdominal pain. Vomiting.	Laparotomy immediate. Rupture not found.	D	Complete rupture jejunum. Laceration of omentum and mesentery.
21	12 M	(*a*) 20/10/22 (*b*) 20/10/22 (*c*) 20/10/22	Run over by lorry.	Extreme shock. Abdomen rigid and tender. Vomited a good deal of blood.	No operation.	D	Complete rupture of jejunum. Laceration of liver and pancreas.
22	29 M	(*a*) 12/2/23 (*b*) 12/2/23 (*c*) 14/2/23	Crushed between cart and wall.	On admission diffuse pain, no rigidity. Pulse 100. After 24 hours it rose to 120, with signs of peritonitis.	Laparotomy. Enterostomy.	D	Complete rupture of jejunum. Peritonitis and fat necrosis.
23	? M	(*a*) 8/9/99 (*b*) 8/9/99 (*c*) 9/9/99	Run over by trolley.	Much pain, rigidity; liver dullness normal. On following day pulse rose to 142. Dullness developed in lower abdomen.	Laparotomy. Suture.	D	Partial rupture of ileum. Much free blood in abdomen.

TABLE I.—THIRTY-FOUR CASES OF TRAUMATIC INTESTINAL RUPTURE—(*Continued*).

No.	Age and sex.	Dates of (*a*) accident, (*b*) admission, (*c*) discharge or death.	Nature of injury.	Symptoms and signs.	Treatment.	Result.	Condition found at operation or post mortem.
24	22 M	(*a*) 4/1/99 (*b*) 4/1/99 (*c*) 5/1/99	Crushed between buffers of train.	Abdomen rigid. Much pain. Liver dullness impaired; dullness in left flank.	Laparotomy 26 hrs. after injury. Resection.	D	Partial rupture of ileum in two places 3 in. apart, about 4 ft. from ileo-cæcal valve. Peritonitis.
25	10 M	(*a*) 10/10/07 (*b*) 10/10/07 (*c*) 29/12/07	Run over by cart.	Abdomen rigid. Much pain. Bruise on right side. Vomited blood. Pulse rose to 124.	Laparotomy on following day. Suture and drainage.	R	Partial rupture of ileum in two places.
26	28 M	(*a*) 18/3/09 (*b*) 18/3/09 (*c*) 31/3/09	Struck by door of goods van.	Much pain, especially in right iliac region. Abdomen rigid and very tender. Pulse 66. Condition same on following day, with some vomiting. Pain and rigidity continued 11 days, when vomiting again started.	Laparotomy 13 days later. Omentum adherent to small rupture of ileum. Separated.	D	Omentum had become adherent to ileum, sealing the perforation but producing intestinal obstruction 12 days later.
27	42 M	(*a*) 6/1/13 (*c*) 9/1/13	Struck in abdomen by heavy weight of coal.	Abdomen very rigid. Pulse 84. Vomiting persisted and pulse-rate rose to 130.	Laparotomy. Suture.	D	Rupture of ileum for about half its width at the anti-mesenteric border. Peritonitis.
28	51 M	(*a*) 28/1/20 (*b*) 28/1/20 (*c*) 15/3/30	Kicked on abdomen.	Much pain and thirst. Abdomen rigid. No vomiting. Pulse 88.	Laparotomy 2 hrs. after admission. Suture, drainage.	R	About 2 pints of blood-stained fluid in the abdomen; two small partial ruptures of ileum about 2 ft. from ileo-cæcal valve on mesenteric border.
29	? M	(*a*) 20/4/99 (*b*) 20/4/99 (*c*) 21/4/99	Hit on abdomen by iron pipe.	Much pain, marked rigidity. Liver dullness normal.	Laparotomy on following day. Suture.	D	Complete rupture of ileum.
30	49 M	(*a*) 31/8/03 (*b*) 31/8/02	Run over (intoxicated) by brewer's dray.	Much collapse.	Operation refused.	D	Complete rupture of ileum about 4 ft. from ileo-cæcal valve. Other viscera normal. Little peritonitis.
31	3 F	(*a*) 25/10/10 (*b*) 26/10/10 (*c*) 29/10/10	Run over by light cart.	Much pain. Bruising on left side. Persistent vomiting. Pulse rose from 114 to 160.	Laparotomy. Suture. Resection and anastomosis with Murphy's button.	D†	Two small ruptures of small intestine. At one point mesentery separated from bowel, which had become gangrenous. Resection necessary.
32	11 M	(*a*) 22/7/99 (*b*) 22/7/99 (*c*) 22/7/99	Run over by cart.	Abrasion of abdominal wall. Marked rigidity. Impaired liver dullness.	Laparotomy 2 hrs. after injury. Resection of 12 in. of bowel. Anastomosis.	D	Two partial ruptures of small intestine.
33	30 M	(*a*) 4/10/04 (*b*) 4/10/04 (*c*) 4/10/04	Knocked down by railway engine.	Contusion of lumbar muscles on right side, and multiple fractures of lumbar spines.	No operation.	D	Fracture dislocation of third lumbar vertebra. The only intra-abdominal injury was one small partial rupture of small intestine.
34	26 M	(*a*) 24/7/98 (*b*) 24/7/98 (*c*) 25/7/98	Thrown from van, both wheels passing over abdomen.	Admitted with fracture of pelvis.	,, ,,	D	Rupture of anterior wall of cæcum. Fractured pelvis.

D = death. R = recovery. * 7½ hours after injury. † From obstruction by button.

In some cases, too, it seems to have been responsible for death even after an early and satisfactory operation before the onset of peritonitis.

Rigidity.—This sign was almost as constant as pain, and usually the abdomen was rigid from the onset. There is no mention in any case of persistent local rigidity.

Of the remaining signs and symptoms none were as constant as the above three, and most commonly they indicated only the onset of peritonitis. Of these latter the steadily rising pulse-rate was the most characteristic, and since this is only a relatively late indication of rupture, while pain, shock, and rigidity of the abdomen may all be present without serious intra-abdominal damage, there is no escaping the conclusion that early diagnosis is almost impossible. The surgeon must be guided more by a general consideration of the clinical picture than by the presence or absence of any particular sign.

It is commonly believed that the normal area of liver dullness is to some extent impaired in intestinal rupture, certainly in a great many cases, if not in all; it is interesting to note, therefore, that in only three of the 34 patients was this the case. In many cases, it is true, no mention is made of its presence or absence, but probably in the majority of these it was absent. On the other hand, in several cases it is definitely mentioned that the liver dullness was normal, so that little or no reliance can be placed upon its absence. Although small quantities of gas must escape from the bowel immediately after its rupture, it is unlikely that there is ever sufficient gas present, in the small intestine at any rate, to alter appreciably the relation of the liver to the abdominal wall. Such small quantities of gas have occasionally been seen in an early X ray examination of the abdomen, appearing as a localised pneumo-peritoneum, and the possibility of demonstrating the presence of free air by this means should always be considered. It is a great pity that this valuable aid to early diagnosis is not more commonly invoked in every case of doubt.

Mortality.

Of the 34 cases recorded, 3 refused operation, leaving for consideration 31. Of this number 7 recovered and 24 died—a mortality of nearly 78 per cent. The successful cases are given in Table II.

That no case of rupture of the stomach or duodenum recovered is accounted for by the fact that injury to these structures was in each case complicated by some other severe laceration, usually intra-abdominal. Of the 15 cases of injury to the jejunum, one case refused operation, and of the remaining 14 five recovered. Of the 8 cases of rupture of the ileum, one also refused operation, and of the remaining seven 2 recovered. There does not appear to be, therefore, any great difference in the mortality of ruptures of the jejunum and ileum respectively, although it might have been supposed that the contents of the latter are usually more septic, and peritonitis therefore earlier in its appearance. In all the successful cases, with the exception of one where Murphy's button was used, it will be noticed that simple suture of the rupture was the only surgical procedure necessary. In the three cases where resection was undertaken the patient died. In only one case was enterostomy performed, and in this case also the patient died.

TABLE II.

Case No.	Situation of rupture.	Nature of operation.	When performed.
8	Duodeno-jejunal junction.	Suture of rupture. No drainage.	Not recorded.
13	Jejunum, 5 in. from commencement.	,, ,,	"Following day."
14	Jejunum, 18 in. from commencement.	Suture of rupture. Drainage.	15 hours after injury.
15	Jejunum, high up.	,, ,,	Not stated; at least 21 hours after injury.
16	Jejunum completely severed.	Murphy button anastomosis.	2¾ hours after injury.
25	Ileum, in 2 places.	Suture of each rupture and drainage.	Following day.
28	,, ,,	,, ,,	Not stated. 2 hours after admission.

Note.—By drainage is meant drainage of the peritoneal cavity.

In the successful cases the time factor, so highly significant in the perforation of a gastric or duodenal ulcer, does not appear to be of so great importance, for although in one case operation was undertaken within two and three-quarter hours of the injury, in one case it was delayed 15 hours, and in another at least 21 hours, while in a further two cases the abdomen was not explored until the following day. Regarding rupture of the small intestine as a whole, of a total of 26 cases the continuity of the bowel was completely severed in 9. Of these one refused operation and of the remainder only one recovered. Of the 17 cases in which the continuity of the bowel was only partially divided, one again refused operation, but of the remainder six recovered. It is clear, therefore, that the mortality of the second group is considerably less than that of the first, and since peritonitis does not seem to have been more marked in one than in the other, it is reasonable to assume that the shock associated with the more severe injury is very largely responsible for this disproportion.

The shock always associated with intestinal rupture, if at all severe, tends to become worse as time goes on, and offers almost insuperable difficulty in the treatment of these cases. In extreme cases the patient dies, even after an early and otherwise successful operation, while in its less severe degrees it obscures the whole clinical picture and masks the onset of peritonitis. A mortality of 78 per cent. is certainly enormous, and there can be little doubt that early exploration of the abdomen would reduce this to a considerable extent. At the same time, however, while every attempt in this direction should be made, it is doubtful whether in the present state of our knowledge a large percentage of recoveries can ever be attained.

I am much indebted to the members of the surgical staff of the hospital for their kind permission to publish these cases.

A CASE OF COMPLETE DECEREBRATE RIGIDITY IN MAN,

WITH OBSERVATIONS ON VARIOUS REFLEX REACTIONS.

By F. M. R. WALSHE, M.D., F.R.C.P. Lond.,
NEUROLOGIST IN THE MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL, AND ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN-SQUARE, LONDON.

In a recent paper[11] the writer discussed the question of Sherrington's decerebrate rigidity from the point of view of its occurrence and recognition in the human subject, and expressed the conclusion that while in the spasticity of hemiplegia and of the extended form of paraplegia we have a clear example of muscular hypertonus physiologically identical with that observed in the decerebrate animal, yet, so far, clinical neurological records contain no completely satisfactory account of a case of "decerebrate man." For the most part the cases to which this diagnosis has been attached during the past two years are examples of different varieties of extrapyramidal syndrome, or of tonic fits, none of which conditions can rightly be identified with Sherrington's decerebrate rigidity.

In these circumstances it may be of interest to place on record the following case, which is a closer approximation to the experimentally produced condition in question than any the writer has encountered in the human subject. Not only was the hypertonus physiologically identical with that described by Sherrington, but there were present Magnus and de Kleijn's tonic neck reflex and also a form of interaction between tonic and phasic reflexes, both of which are a normal accompaniment of the rigidity in animals. Further, the clinical picture was free from complication by those irregularities of respiratory and cardiac activity and by tonic fits, which are in all probability due to gross disturbances in the blood-supply of the brain stem, and are no part of true decerebrate rigidity.

The patient was an unmarried woman of 23. She was admitted to hospital complaining of blindness of sudden onset seven days previously. Up to the morning on which she awoke to find herself deprived of vision she had been at her usual work, but she stated that during the year preceding she had suffered from occasional "bilious attacks with headache," which she had not regarded seriously.

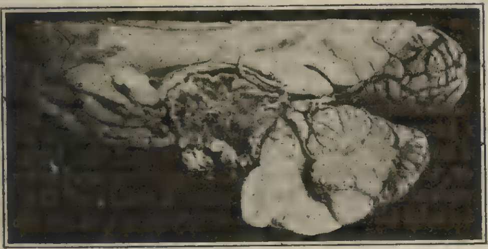
Condition on Examination.—The patient was alert, with normal intelligence, emotional tone, speech, development, and physique. There was total blindness in both eyes, no perception of light remaining in either; the discs showed intense papillœdema with commencing secondary atrophy, and the pupils were dilated and inactive, the cranial nerves being otherwise normal. The motor and sensory systems were normal. The tendon-jerks were brisk and equal on the two sides, the abdominal reflexes sluggish on both sides, and there was a bilateral extensor plantar response.

Operation.—A right-sided temporal decompression was performed, revealing a great increase of intracranial tension, but no other abnormality. A week later she was noted to have a well-marked left hemiplegia, with commencing flexor spasticity in the arm. There was considerable bulging of the scalp over the bone defect.

Course of Case.—During the second week after operation she gradually lapsed into a state of semi-coma, in which she could neither answer questions nor carry out simple orders. However, there was ample motor response of the right limbs to such stimuli as pinching or pin-prick. She remained thus for about two weeks, towards the end of which a right hemiplegia began to develop. Finally, in the fourth week complete double hemiplegia obtained. The patient lay motionless in bed. She was unable to swallow and was nourished by means of œsophageal feeds. The temperature was consistently below normal, ranging from 96° F. in the morning to 97° in the evening. The pulse was regular in force and frequency and averaged 84 per minute. Respiration was regular and unembarrassed and of a rhythm of 18. The blood pressure ranged between 130 and 140 mm. of mercury. During the last week of life the coma deepened, the tonic reflexes to be described failed, the rigidity waned, the tendon-jerks disappeared, and tonic fits, cardiac and respiratory irregularities developed. The blood pressure slowly sank during the terminal stage.

Post-mortem Examination.—A nodular mass was revealed, presenting at the base of the brain in the inter-peduncular space, and stretching and separating the optic tracts. It was strictly median in position, and on its under-surface and continuous with it was the pituitary body, which was of normal size. Median sagittal section of the brain exposed the tumour, as depicted in Fig. 1. The pituitary body was cystic and the large cavity contained in it was continuous with a large cavity in the lower portion of the growth. The tumour was sharply marked off from the brain tissue, and a fine membrane surrounded it as it filled the third ventricle. It was lobulated in structure and contained numerous small cystic cavities and calcareous masses. It clearly belonged to the well-defined group of supra-pituitary tumours recently discussed by Greenfield, Armstrong,[4] [5] and others. Histologically, also, it conformed to the description given by these authors, In addition, there was marked dilatation of the lateral ventricles. It seems probable that an acute secondary hydrocephalus was the cause of the rapid onset of symptoms in the first place, and that finally this and the pressure of a large mass in the middle line produced the effect of "decerebration" by compressing the structures in the anterior part of the brain stem and by cutting off the cerebral hemispheres from functional connexion with lower levels. The thoracic, abdominal, and pelvic viscera were all normal.

FIG. 1.



Sagittal section of the brain, the mesial aspect of the left half presenting, and revealing a supra-pituitary tumour which fills the third ventricle. The cystic pituitary can be seen at its lowest part. Histologically, the growth is a myxo-endothelioma.

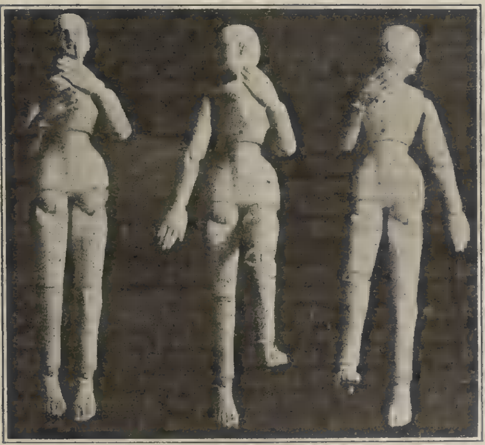
We may now pass to consider the features which led to the conclusion that the patient was a true example of decerebrate rigidity. The course of the illness may be divided into two stages for this purpose: (*a*) the stage of decerebrate rigidity, and (*b*) the stage of failing reflex activity and of tonic fits.

(*a*) *Stage of Decerebrate Rigidity.*

The patient lay motionless and unconscious on her back, with the head in the median position. There was no trace of head retraction. The arms lay across the chest, semi-flexed at the elbows, with the forearms slightly pronated and the wrists and digits flexed. The legs lay extended and adducted with the feet plantar-flexed. There was spasticity of moderate degree in all four limbs, definitely more pronounced in the arms than in the legs. In the former the flexors were concerned, in the legs the extensors (and plantar flexors). In addition to this characteristic selective incidence, the hypertonus showed all the usual features of decerebrate rigidity. Owing to its recent onset, it was extremely plastic, the limbs tending to retain any new posture passively imposed upon them. Nevertheless, on returning to the patient after the lapse of about ten minutes, they were invariably found to have resumed the initial positions above described. Passive stretching of a spastic muscle, the flexors of the forearm or the knee extensors, revealed the familiar "clasp knife" character of the spasticity and experimentally produced decerebrate rigidity, in which after the initial tonic resistance has been overcome the spasm seems suddenly to melt away.[6] [9] The tendon-jerks were all very brisk and presented the tonic prolongation typical of the "spastic" tendon-jerk. In the case of both knee- and supinator-jerks the "step-ladder" shortening of the muscle after each of a series of rhythmically elicited jerks was observed.[11] In short, all the features of decerebrate rigidity were present. The abdominal reflexes were absent, and stimulation of the sole was followed by a flexion reflex consisting of an ample Babinski plantar response, and of a rapid, short-lived flexion at hip and knee of moderate amplitude. Simultaneously, the foot and great toe of the crossed limb plantar-flexed (crossed extension reflex).[8]

Tonic Neck Reflex of Magnus and de Kleijn.—The method of eliciting this reflex and its characters in the human subject I have already described in detail elsewhere.[10] They were very facile in this subject, and obeyed the laws formulated by Magnus and de Kleijn.[5] Two assistants supported the lower limbs above the bed in an attitude of slight flexion at hip and knee, the two arms were slung from the wrist so as to lie just free of the trunk. In these circumstances the observer took the head between his two hands and rotated it to right or to left as desired. The following tonic reactions were observed. When the head was rotated so that the face looked over the right shoulder, the right arm, after a latent period of about two seconds, slowly extended at the elbow, the whole limb abducted, the forearm went into increased pronation. The wrist and digits remained immobile. The right lower limb slowly and actively extended, the foot plantar-flexing. *The left arm* (that on the side to which the occiput was directed) simultaneously went into full flexion at the elbow so that the hand came into the neighbourhood of the neck, the forearm supinated, and the wrist and digits remained immobile. The left leg moved very slightly into an attitude of increased flexion at hip and knee and the foot moved up slightly into dorsiflexion. The limbs retained these new attitudes as long as the head remained with the face looking to the right, but as soon as it was again rotated so that the face came to look over the left shoulder the relative attitudes of the right and left limbs were reversed. Slowly the right arm and leg took up a posture of flexion, while the left arm and leg slowly extended, taking up an attitude like that previously held by the right limbs. When the leg was allowed to lie extended on the bed the foot on the side towards which the face looked went into full plantar flexion. These attitudes and their relation to the position of the head are illustrated in Fig. 2 by photographs of a lay figure.

FIG. 2.



Photographs of a lay figure representing the attitude of the patient's limbs in the three positions of the head—in centre, turned to right, and turned to left. Actually, the patient's wrists and digits were flexed.

Interaction of Tonic Neck Reflex and of Flexion Reflex of Lower Limb.—Sherrington[7] has shown that tonic or postural reflexes are very readily overset by phasic reflexes—that is, by reflex movements of nociceptive character, but that the initial posture of the reacting limb is at once restored by an active return of the tonic reflex originally in possession of the musculature. Thus the extensor rigidity of the hind limb is temporarily inhibited by the flexion reflex, but as soon as active flexion ceased the limb returns to extension by an active "extensor rebound." Further, following the momentary inhibition, extensor tone may be increased in intensity ("post-inhibitory exaltation"). Clearly the force of the rebound and the degree of exaltation will depend upon the intensity of extensor tone originally present, and under different grades of extensor tone the flexion reflex may be expected to show different characters in respect of amplitude and time relations. This is simply an expression of that interaction of tonic and phasic reflex which is a normal element in coördination. Now, in Magnus and de Kleijn's tonic neck reflex we have a method of varying the degree of extensor hypertonus at will from moment to moment, and therefore the form of the flexion reflex may be modified by head rotation. Indeed, Graham Brown[3] has found that in the decerebrate animal the active modification of the posture of the reacting limb may cause a complete reversal of the form of a reflex movement ("reflex reversal"). The present subject afforded an excellent opportunity of investigating this point, and since, as is now widely accepted, the Babinski plantar response is simply the dorsiflexion component of the flexion reflex of the lower limb of man, it may be used as an index of modifications in the flexion reflex.[12]

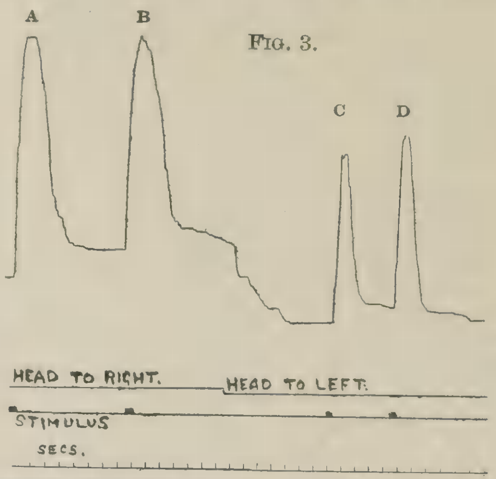


FIG. 3.

Graphic records of four successive Babinski responses elicited from the left sole; A and B were elicited with the head turned to the right—i.e., with face looking to right; C and D with head turned to the left. Upward movement = dorsiflexion, downward movement = plantar flexion. Sole stimulation, head rotation, and time are recorded below. It can be seen that spontaneous plantar flexion of the foot and hallux followed rotation of the head to the left, and that the two responses obtained with the head in this position are less ample and of shorter duration than the first two, which were obtained with the head turned to the right—i.e., with minimal extensor hypertonus in the limb.

Accordingly the present subject showed a marked change in the plantar response when the head was rotated from one lateral position to the other. Thus when the head was rotated so that the face pointed to the right shoulder, stimulation of the left sole evoked an ample Babinski plantar response with dorsiflexion of the foot and some flexion at hip and knee. The return or extension (plantar flexion) phase of the response was slower than the active flexion (dorsiflexion) phase and was incomplete. If the head was then rotated so that the face pointed to the left shoulder, the foot plantar flexed. The plantar responses subsequently elicited were less ample than those just described and the return, or extension phase, was rapid and complete. In these circumstances the extensor spasticity of the limb was maximal, and "extensor rebound" cut short the flexion reflex and rapidly restored the initial posture of the limb. Similar examples of this phenomenon have been described by the writer elsewhere, and apart from their obvious practical interest they have a great theoretical importance. These variations in the plantar response are graphically recorded in Fig. 3.

(*b*) *State of Failing Reflex Activity and of Tonic Fits.*

During the last five or six days of the patient's life the condition we have described gave place gradually to a progressive failure of reflex activity and to deepening coma. The temperature began to swing from 96° in the morning to 101° in the evening. The pulse and respiration rates became rapid and variable. The blood pressure sank below 100. The Magnus and de Kleijn reflexes failed completely five days before death and the rigidity waned, but never entirely disappeared in the arms, which retained the posture described. The tendon-jerks disappeared and the flexion reflex on stimulation of the soles diminished in amplitude and force. Twice during the last days of the stage we have described as that of decerebrate rigidity the patient was noticed suddenly to become extremely rigid in her customary posture, and to become very red in the face. These attacks were of momentary duration. During the last week, however, they became of great frequency and intensity. The respiratory muscles became fixed, and the limbs were so rigid that no tendon reflexes could be elicited. These attacks lasted for from 15 to 20 seconds and passed off as suddenly as they developed, the patient sinking down into the bed. In the more severe ones the head retracted forcibly. A very large number of these tonic fits were noted, and doubtless many more escaped observation. They ceased entirely during the last 24 hours of life, when the patient was obviously moribund.

Comments on the Case History.

A close examination of this case history reveals but two points of defect from the complete picture of decerebrate rigidity as seen in the experimental animal. The first of these is the flexion posture of the upper limbs, the second the retention of temperature control. In earlier papers[9] the possible explanation of the flexed position of the upper limbs in hemiplegia has been discussed. It may be traced to the fact that in man the forelimbs are no longer simple locomotor props and have taken on new and highly complex functions under the influence of the cerebral cortex. In consequence we should not expect them to take up the extensor attitude of standing. Secondly, the animal after transection of the brain stem in the region of pons or medulla loses all temperature control, and, as Bazett and Penfield have shown,[2] this fact is the chief obstacle to keeping the decerebrate preparation alive for more than a few hours. It is clear, therefore, that our patient was not completely "decerebrate," and that to this fact we owe our opportunity of observing over so long a period a clinical picture identical in every other essential with experimentally produced decerebrate rigidity.

With the various theoretical considerations arising out of the presence of Magnus and de Kleijn's tonic reflexes, and of the interaction between these and the flexion reflex of the lower limb, it is not proposed to deal here, for they are discussed fully elsewhere.[10, 12] Tonic labyrinthine reflexes were not sought for, since the handling of the patient which their investigation involves was not thought desirable.

A few observations on the stage of failing reflex activity may be made. It is noteworthy that it was at this stage, when the phenomenon of decerebrate rigidity was finally disappearing, that tonic fits and the respiratory and cardiac irregularities which always accompany them made their appearance. It would be difficult to find a more striking demonstration of the fundamental difference between tonic fits and true reflex decerebrate rigidity than this sequence of events provides. Lastly, a comparison of the condition observed in this patient during the stage of decerebrate rigidity with the types of muscular spasm seen in the extra-pyramidal syndromes should, if our identification of it be correct, finally dispose of the view now widely current that Parkinsonian rigidity, chorea, and athetosis can in any way be correlated with this clearly defined group of reflex phenomena.

(*Continued at foot of next column.*)

THE RELATION BETWEEN THE GROWTH-PROMOTING AND ANTI-RACHITIC FUNCTIONS OF CERTAIN SUBSTANCES.

BY H. GOLDBLATT, M.D. McGILL,
BEIT MEMORIAL RESEARCH FELLOW;
AND
S. S. ZILVA, D.SC. LOND.,
ASSISTANT, LISTER INSTITUTE.

THE study of the vitamins during the last few years has thrown a new light on the cause of the general therapeutic value of cod-liver oil. Soon after the description of the fat-soluble A food factor by McCollum and Davis,[1] Osborne and Mendel[2] showed that cod-liver oil contains this principle. Mellanby[3] demonstrated the anti-rachitic function of some food-substances containing fat-soluble A. Zilva and Miura[4] were able to prove that cod-liver oil contains it in great abundance, namely, about 200 times as much as butter, which fact, in their opinion, was responsible also for the disparity in the therapeutic action of the two substances, especially in the prevention and cure of rickets. Soon after, McCollum, Simmonds, Shipley and Park[5] brought forward experimental evidence that the calcium depositing property of cod-liver oil was much greater than that of butter, and they advanced a theory that the calcium depositing or anti-rachitic factor and the fat-soluble A factor were not one and the same principle. It was pointed out at the time by one of us (S. S. Z.)[6] that these investigators were not taking sufficiently into consideration the great difference in the fat-soluble vitamin content of cod-liver oil and butter, and that the disparity in the anti-rachitic functions of the two substances could be equally explained by that fact. Recently many researches have shown that light can aid the promotion of growth as well as induce the deposition of calcium in bone. This parallelism also pointed to the existence of one principle. McCollum, Simmonds, Shipley and Park[7, 8] have since produced further evidence in support of their hypothesis. Striking as their evidence was, it was considered that their results would have been more convincing if stricter quantitative methods had been employed, and if the growth-promoting property of the substances had been taken as a criterion of the fat-soluble A factor instead of the anti-xerophthalmic property, which, in our opinion, is not so suitable for comparative work, because it is a less constant manifestation in rats subsisting on a fat-soluble A deficient diet. However, the results recorded below tend to confirm the hypothesis of McCollum and his collaborators that the two principles are not the same, their destruction by heat and oxidation and their quantitative distribution being different.

Experimental.

In the experiments an attempt was made: (i.) To ascertain whether the inactivation of the growth-promoting and anti-rachitic functions by heat in the presence of air proceeded at the same rate. For this purpose cod-liver oil was investigated. (ii.) To determine the quantitative distribution of the alleged two factors. For this a substance very different in character from cod-liver oil, such as spinach, was employed.

1. *Inactivation of the Growth-promoting and Anti-rachitic Functions of Cod-liver Oil by Heat and Aeration.*—In this experiment about a litre of cod-liver oil of known growth-promoting and anti-rachitic properties was heated in an oil-bath at a constant temperature of 120° C., whilst a continuous current of air was aspirated through it. Portions of the cod-liver oil were removed 6, 12, 18, and 24 hours after it had reached 120° C., and in these samples the growth-promoting and anti-rachitic properties were estimated. For the estimation of the fat-soluble growth-promoting factor the quantitative method of Zilva and Miura[4] was employed. The fat-soluble deficient diet used consisted of:—

Inactivated casein ..	20 g.	Decitrated lemon-juice	5 c.cm.
Starch	50 „	Marmite	5 g.
Cotton-seed oil	15 „	Distilled water ..	50 c.cm.
Salt-mixture*	5 „		

* McCollum,[9] No. 185.

In the investigation of the anti-rachitic property of the oils and other substances it was decided to study the preventive rather than the curative action. McCollum and collaborators based their conclusions upon a study of the curative property of the substances they investigated, and recommend it as the best method. Both methods were tried, but the preventive one was considered the more suitable for quantitive work and easier to standardise. Using macroscopical and microscopical appearance as well as calcium content of the bones as the criteria upon which to base a diagnosis, it was found, in a quantitative study such as this, to be the more reliable method upon which to base conclusions.

The rickets-producing diet employed was No. 3143 of McCollum and collaborators, which is constituted as follows:—

Diet No. 3143.

Wheat	33 g.	Sodium chloride ..	1·5 g.
Maize	33 „	Calcium carbonate ..	3·0 g.
Gluten	15 „	Distilled water† ..	60·0 c.cm.
Gelatin	15 „		

† Added to make a paste.

This diet is deficient in phosphorus and the fat-soluble organic factor. In another study by one of the authors (H. G.) about 150 rats, similar in origin and age to those employed in this investigation, were kept on the above diet, and, without a single exception, they developed severe rickets in four weeks. Four weeks, therefore, was adopted as the standard experimental period. Since the diet employed is low both in phosphorus and anti-rachitic factor, absolute normality of the bones could not be expected as a result of the addition to it of the organic factor only. However, in preliminary trials it was found that the administration daily of an adequate amount of cod-liver oil to rats on this diet had a profound effect on the development and calcification of their bones. Though they were not absolutely normal, yet neither grossly nor histologically did they show any resemblance to rickets. Although the rickets-producing diet employed was of different composition from the fat-soluble A deficient one used in the tests for growth-promotion, it is to be pointed out that the conclusions are based only upon the relative *rate* at which each function is destroyed by heat and oxidation, and not upon the relative *quantity* of each factor contained in the various substances.

Table I. gives a comparative description of a typical rat kept on diet 3143 for four weeks, and of one on the same diet plus a daily minimal protective dose (3·3 mg.) of cod-liver oil. The most definite and most reliable criterion for the final diagnosis was the histology, but the gross appearance and chemical analysis of the bones were of material aid in deciding the end-point in the titration of the substances. The microscopical investigation often demonstrated pathology not recognisable macroscopically, so that what appeared doubtfully positive protection in the gross always turned out definitely negative upon histological examination.

TABLE I.

Control rats on diet 3143 for four weeks. Severe rickets.	Rats on diet 3143 for four weeks that received daily a minimal protective dose of cod-liver oil. No rickets.
Macroscopical.	
1. Deformed chest.	1. Chest full and rounded.
2. Enlarged costo-chondral junctions and epiphyses.	2. No enlargement of costo-chondral junctions or epiphyses.
3. Very indistinct, disorganised costo-chondral line.	3. Costo-chondral lines straight and distinct.
4. Fractures of bony portion of ribs.	4. No fractures.
5. Bones very pliable.	5. Bones very much firmer than those of control, but more brittle than normal.
Microscopical.	
1. Deformity of rib near costo-chondral junction.	1. No deformity.
2. Very great proliferation of zone of provisional calcification. (25–50 layers of hypertrophic cartilage cells.)	2. Zone of provisional calcification consisting of 3–7 layers of hypertrophic cartilage cells.
3. No calcium deposit in zone of provisional calcification.	3. Moderate to very good deposit of calcium in zone of provisional calcification.
4. Disorganisation of zone of provisional calcification.	4. No disorganisation of zone of provisional calcification.
5. Wide rachitic metaphysis consisting mainly of osteoid and of uncalcified cartilage.	5. No rachitic metaphysis. Trabeculæ thin and short, but straight and well calcified.
6. Very great increase of endosteal and periosteal osteoid of cortex.	6. Only the physiological amount of cortical osteoid.
7. Callus of fracture consisting mainly of osteoid, uncalcified cartilage, and fibrous bone-marrow.	7. No fracture.
Calcium Content of Bones.	
Average % wet, 4·39. Average % dry, 11·43.	Average % wet, 6·77. Average % dry, 14·81.

Including the number used for the preliminary tests 208 rats were used in this part of the investigation. For economy of space the protocols of the rats will not be included in this report. The rats were put on the rickets-producing diet at the age of from 25 to 28 days and weighing about 40 g. Two sets of controls were used in the titration of every oil: one set receiving the rickets-producing diet alone, the other the same diet supplemented by a daily dose of the crude oil known to protect against the development of rickets. The first titration of the potency of an oil was made by using quantities within wide limits—viz., 2·25 mg., 22·5 mg., and 225·0 mg. daily. If one of these doses gave protection, then the final value was determined by titrating with quantities at close intervals between the first positive result and the negative one immediately below it. In the case of the growth-promoting experiments four animals were employed for every dose, and the minimal quantity was arrived at by a similar spacing of doses.

The final values given in Table II. for the minimal anti-rachitic and growth-promoting doses of the various oils represent in every case the mean between the first definitely positive result in the final titration and the negative one immediately below it, both of which are also given in the table.

The chart compares the potency of the above oils by giving the number of minimal growth-promoting and rickets-protecting doses per gramme of every oil. It shows very well that although the initial potency of the crude oil was somewhat greater for growth-promotion than for protection against rickets, yet the growth-promoting function suffered more rapidly from oxidation at 120° C. than did the anti-rachitic function. In the specimen removed after 18 hours of heating and aeration the growth-promoting function was practically destroyed, while the anti-rachitic power was still retained in a moderate degree. In the 24-hour specimen of oxidised cod-liver oil neither function could be detected.

TABLE II.

Type of oil.	Anti-rachitic function.			Growth-promoting function.

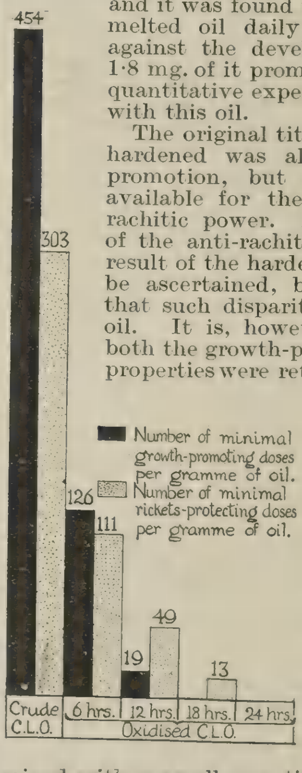
24 „	450·0*	—	—	1000·0*	—	—

* Indicates that this dose definitely failed, and that a larger dose was not tested.



For additional information a sample of hardened cod-liver oil was also tested for the two functions, and it was found that about 33·7 mg. of the melted oil daily were potent to protect against the development of rickets, while 1·8 mg. of it promoted growth. An elaborate quantitative experiment was not performed with this oil.

The original titre of the oil before it was hardened was also 1·8 mg. for growth-promotion, but no specimen of it was available for the estimation of the anti-rachitic power. How much deterioration of the anti-rachitic potency occurred as a result of the hardening could not, therefore, be ascertained, but it is hardly possible that such disparity existed in the original oil. It is, however, very significant that both the growth-promoting and anti-rachitic properties were retained in a high degree by the hardened oil.

2. *The Growth-Promoting and Anti-rachitic Functions in Spinach.*—Spinach was used as the plant source of the organic factor. The fresh leaves were ground to a paste and administered in quantities from 0·1 g. to 3·0 g. daily to rats that had stopped growing on the fat-soluble deficient diet and to rats on the rickets-producing diet No. 3143. The daily dose of spinach was mixed with a small quantity of the diet and served first. When that was consumed the rat was allowed to have the rest of the ration. The minimal growth-promoting dose was found to be between 0·1 and 0·25 g., while even 3·0 g. daily, the maximum dose which it was found practicable to administer (about 30 per cent. of the diet), did not have the slightest effect in

promoting calcium deposition. The animals that received the spinach were as severely rachitic as the controls. This result is similar to that of McClendon,[10] who found that from 0·1 to 0·5 g. of dried spinach cured ophthalmia, while it showed no evidence of affording protection against the development of rickets even when it formed as much as 75 per cent. of the daily diet. Zucker [11] also showed that an alcoholic and ether extract of spinach, while it possessed the power to promote growth, was unable to protect against the development of rickets.

Summary.

1. The growth-promoting and anti-rachitic properties of cod-liver oil are inactivated at different rates by heat in the presence of air.

2. There is a very great disparity between the growth-promoting and the anti-rachitic potency of spinach.

3. A certain sample of hardened cod-liver oil has been found to possess high growth-promoting and anti-rachitic activity.

4. The above observations give further support to the hypothesis of McCollum, Simmonds, Shipley, and Park that the anti-rachitic and the fat-soluble A factors are different principles.

To Prof. C. J. Martin we give our sincere thanks for very helpful advice and criticism during this investigation. A part of the expenses of this research was defrayed from a grant made by the Medical Research Council, to whom our thanks are also due.

PRENATAL CARE AND PUERPERAL MORTALITY.*

BY A. LEYLAND ROBINSON, M.D. LOND., F.R.C.S. ENG.,

HONORARY ASSISTANT SURGEON, MATERNITY HOSPITAL AND HOSPITAL FOR WOMEN, LIVERPOOL; VISITING OBSTETRICIAN, BROWNLOW HILL INFIRMARY.

THE remarkable fact that there has been no appreciable reduction in the maternal mortality of childbirth during the last 50 years is capable of two possible explanations: either obstetric medicine has made no progress or the modern advances are not in general use. The first suggestion is obviously untrue, for no one can doubt that valuable additions have been made to the treatment of the disorders and complications of pregnancy and the conduct of difficult labour, and it can easily be shown that these advances are competent to reduce the puerperal mortality if and when they are properly employed. But it has not yet been realised that modern methods are essentially preventive methods, and that to be successful they must be initiated during the prenatal period. Thus, the early prophylaxis of the toxæmias, contracted pelvis, and puerperal sepsis gives almost uniformly good results, whereas the latter continue to be disappointing if treatment is delayed until the disease or mechanical difficulty has reached an advanced stage.

But it is absurd to argue that modern methods have failed because the mortality is still high in cases of convulsive eclampsia, ruptured uterus, or puerperal septicæmia; on the contrary, such dangerous complications are almost impossible if prenatal care is exercised, and therefore the development of such advanced lesions is per se strongly suggestive of the neglect of modern methods. Some degree of failure to recognise and treat warning prodromata is inevitable so long as midwives continue to supervise from 50 to 75 per cent. of all pregnancies, and while the general public remain indifferent, if not hostile, to routine prenatal work; but the very inadequate training of medical students and the exigencies and established usages of general practice are also responsible factors.

As a direct consequence the general practitioner is commonly compelled to undertake the treatment of obstetric difficulties in emergency without adequate assistance and often under grossly unsuitable conditions; or the case is admitted to hospital after unsuccessful interference at home, sometimes in extremis, or at least under circumstances highly "suspect" and dangerous, and which, in spite of the resources of hospital technique and equipment, may completely discount the value of otherwise safe and effective treatment.

Attention has already been drawn to the subject in a report on Maternal Mortality published by the Local Government Board in 1915. After an exhaustive inquiry the following conclusions were expressed:—

> (1) The majority of deaths are caused by puerperal fever, hæmorrhage, and convulsions, most cases of which are well within the range of preventive medicine.
>
> (2) Local differences in total mortality are in the main caused by differences in availability of skilled assistance when needed during pregnancy and at and after childbirth.
>
> (3) Puerperal fever has been substantially eliminated from lying-in hospitals, but otherwise there is a remarkable uniformity in its distribution.

Papers on this subject have usually been written from the hospital standpoint, and fail to recognise, and therefore neglect, the totally different and much more difficult conditions of general practice. Many suggested remedies are impracticable because they cannot be applied to the majority of cases. Admittedly it is impossible to produce uniformity of skill and technique, just as it is unnecessary to provide so-called surgical surroundings for ordinary uncomplicated labour; but it is neither unreasonable nor impracticable to demand that abnormal pregnancy and complicated labour should be diagnosed as quickly and treated as carefully as other major surgical emergencies. Prenatal care is the only method of attaining this object, and fortunately a simple one, for its elementary principles are not beyond the powers of the average midwife, and its teaching can be applied as easily in general as in hospital practice; and not until this method is universally adopted can any serious reduction of the puerperal mortality be effected. To support this contention it is necessary to demonstrate three groups of facts: (1) the causes of death in childbirth; (2) the extent to which these morbid processes are associated with recognisable warning symptoms during pregnancy; (3) the proof that such prodromata are largely amenable to preventive treatment.

Causes of Maternal Death in Childbirth.

At Brownlow Hill Infirmary, Liverpool, since 1880 there have been 159 deaths amongst 14,000 cases delivered in the maternity wards. The causes of death were generally determined by autopsy, and may be classified as follows:—

Puerperal Sepsis (53).—Septicæmia, 18; septicæmia and syphilis, 6; septicæmia and gonorrhœa, 1; peritonitis, 16; septic pneumonia, 5; erysipelas, 2; cellulitis, 1; phlebitis, 1; salpingitis, 2; pyelitis, 1. (*a*) Most of these labours were instrumental or otherwise complicated. (*b*) Patients belonged to the lower strata of society and showed a high incidence of venereal infection. (*c*) Modern control of sepsis in hospital is shown by the following figures : 1880–90, 30 deaths ; 1890–1900, 13 deaths ; 1900–10, 7 deaths ; 1910–20, 3 deaths. (*d*) The many different types of fatal sepsis shown emphasises the importance of honesty in diagnosis and suggests that if accurate notification became general the amount of puerperal infection would exceed the high figures now apparent.

---

* A paper read before the Liverpool Medical Institution.

Hæmorrhages and Accidents (26).—Post-partum hæmorrhage, 8 ; post-partum hæmorrhage and sepsis, 4 ; ante-partum hæmorrhage, 4 ; placenta prævia, 4 ; ruptured uterus, 5 ; craniotomy (shock), 1.

Toxæmias (17).—Jaundice, 1 ; albuminuria (nephritis), 2 ; eclampsia, 14.

Intercurrent or Pre-existing Organic Disease (63).—Pneumonia, 12 ; bronchitis, 11 ; phthisis, 17 ; heart disease, 9 ; typhoid fever, 3 ; meningitis, 2 ; cerebral abscess (latent before delivery), 1 ; cerebral tumour, 1 ; insanity (hunger strike), 1 ; scarlet fever, 1 ; irritant poison and alcoholism (coroner's inquests), 1 each ; carcinoma of cervix, 1 ; cancer of liver, 1 ; tuberculosis of kidney, 1. In a few of these cases pregnancy played a small and insignificant part in producing the fatal result : in a larger number parturition was the dominant factor and the essential cause of death. It is clear that the association of conception and independent organic disease may lead to the formation of a vicious circle of a most dangerous type, and that all such cases require early and vigorous prenatal treatment.

At the Liverpool Maternity Hospital in four recent years there have been 63 deaths amongst 2934 consecutive cases, of which 1239 were complicated.

Hæmorrhages and Accidents (26).—Accidental hæmorrhage, 13 ; placenta prævia, 4 ; post-partum hæmorrhage, 1 ; craniotomy (shock), 1 ; ruptured uterus, 5 ; incarcerated retroverted gravid uterus, 2.

Toxæmias (24).—Eclampsia, 21 ; toxic vomiting, 3.

Intercurrent or Pre-existing Disease (10).—Heart disease, 5 ; pneumonia, 3 ; embolism, 1 ; appendicitis, 1.

Sepsis (3).—Pyelitis, 1 ; peritonitis following Cæsarean section, 1 ; septicæmia (associated with a septic prolapsed uterus), 1. Note that during this period of four years 88 deaths were notified in the city of Liverpool as due to puerperal fever, and that very few of them occurred amongst patients delivered in hospital—i.e., the majority occurred amongst women delivered in their own homes.

Puerperal deaths therefore fall into four groups : (1) Sepsis, commonest among women delivered at home. (2) Hæmorrhages and accidents, commonest in maternity hospitals. (3) Toxæmias, commonest in maternity hospitals. (4) Intercurrent or pre-existing organic disease, commonest in Poor-law hospitals.

Amount of Prenatal Care received by 60 Fatal Cases at the Liverpool Maternity Hospital.

A brief reference to this series will not only disclose the extent to which preventive measures were employed (or neglected) in these particular cases, but will serve as a rough standard of the present development of prenatal practice.

Toxæmias.—Eclampsia : All the 21 fatal eclamptics were brought into hospital after the onset of convulsions : five only had any sort of preventive treatment. One attended the out-patient department but persistently refused to come into hospital, although pressed to do so. The second had symptoms for six weeks and called in her doctor five days before the fits commenced. The third had symptoms for two weeks and treatment at home for two days. The fourth attended the out-patient department, was admitted after delivery with post-partum eclampsia, and died four weeks later from septic endocarditis. The fifth was the only case to develop eclampsia whilst under treatment—at the rest home attached to the hospital—a fulminant type who died 19 hours after the first fit.

Sixteen patents had no preventive treatment whatever, they were admitted (on an average) 10½ hours after the first convulsion, and 15 women died within 12 hours of arrival. An analysis of 142 Liverpool cases of eclampsia presented to the British Congress of Obstetrics, 1921, showed that only 20 (less than 14 per cent.) had received any attention prior to the onset of convulsions.

Toxic Vomiting.—Three deaths ; all three fatal cases were ill for several weeks without seeking advice, and died two, three, and nine days respectively after admission to hospital.

Accidental Hæmorrhage.—Thirteen deaths. As two women died within two hours and eight women within four hours of admission, the previous history of many of these cases was incomplete ; but only one patient had been attending the out-patient department of the hospital before the onset of bleeding. In most cases, however, the onset of the fatal bleeding was sudden and without warning symptoms.

Placenta Prævia.—Four deaths. All these patients had warning bleedings which they ignored, and were admitted to hospital more than 24 hours after the onset.

Post-partum Hæmorrhage.—One death. This case is an extreme example of the widespread ignorance and indifference of the patients themselves. The woman was a 12-para, who, in spite of a series of hæmorrhages at former labours (A.P.H. once, P.P.H. twice, and adherent placenta three times), had neglected to engage a midwife, much less consult a doctor. Skilled assistance was not obtained until after delivery, and then only after the onset of alarming bleeding. She was moribund on admission to hospital and died 50 minutes later.

Accidents of Pregnancy and Labour.—Nine deaths. Craniotomy for dystocia : One case, dying on admission from shock and hæmorrhage, the result of the repeated and unsuccessful application of forceps to a patient with unsuspected deformity of the pelvis. Ruptured uterus : Four cases, none of them associated with toxæmia or previous Cæsarean section. All had occurred before admission, and were due to the traumatic rupture of healthy uterine muscle—the end-result of obstructed labour. There had been no preliminary or prenatal examination in any of these cases ; the warning signs were therefore unrecognised, and the adoption of modern methods was fatally postponed.

Incarceration of Retroverted Gravid Uterus.—Two deaths. On admission one patient gave a history of two weeks' severe dysuria, the other seven days' anuria. Neither had received any active treatment before arrival at hospital.

Intercurrent or Pre-existing Organic Disease.—Ten deaths : Heart disease, 5 (partial prenatal treatment in two cases, none in 3) ; pneumonia 3, embolism 1, appendicitis 1. (It cannot be claimed that prenatal care would have prevented the fatal result in the last five cases.)

It is not intended to suggest that puerperal mortality will completely disappear when the adoption of early treatment is general ; but there is no doubt that the majority of puerperal fatalities belong to the class of preventable diseases, and therefore the maintenance of the present high puerperal death-rate is primarily due to the neglect of the principles and practice of preventive medicine.

Scope of Preventive Methods in Abnormal Pregnancy and Difficult Labour.

Development of Toxæmia.—In four-fifths of all cases of eclampsia there are prodromal symptoms, either headache, œdema or albuminuria, which may be present for an indefinite period before convulsions appear ; the latter are frequently heralded by other warnings, notably abdominal pain, vomiting, and disturbances of vision. Occasionally there appear to be no danger signals—some patients feel well and have large (i.e., pathological) appetites—but even here a silent or symptomless albuminuria usually precedes the toxic storm. It is no exaggeration to say that persistent albuminuria is as significant in the pregnancy of a primipara as the association of muscular rigidity and abdominal pain in the diagnosis of peritoneal infection. After the development of convulsions the outlook is always serious, for not only has valuable time already been lost, but the disturbance entailed by transit to hospital has a very unfavourable effect on the prognosis of such cases. Sometimes massive cerebral hæmorrhage, which may be an early or even initial disaster whenever the threshold of the convulsive stage is reached, will at once destroy all hope of successful treatment. Although malignant types do occur, it can be stated with confidence that some warning is usually given and that if the urine of all primiparæ were examined regularly—if the albuminuria of pregnancy were a notifiable disease and the necessary hospital accommodation available—the convulsive or dangerous stage of eclampsia would become rare and the mortality negligible. When albuminuria is detected—contamination being eliminated—the patient must be kept under observation, because sudden fluctuations in the albumin content, changes in the blood pressure, diminution in the quantity of the urine or the appearance of abnormal constituents, such as acetone, &c.,

may call for intensive treatment and perhaps the termination of pregnancy. The opinion of the late Dr. J. W. Ballantyne—the acknowledged pioneer of prenatal research—was expressed in the following statement made at the British Congress of Obstetrics in 1922:—

> "Of 800 expectant mothers, albumin was found in 254 cases. All the patients save one received preventive treatment—the one who had no preventive treatment developed eclampsia. He almost implored her to stay in hospital, for her labour was due in a few days, and the distant and near danger signals were present. The woman obstinately determined to go home—and returned with eclampsia. She was the striking exception which, in his opinion, abundantly proved the rule—the rule being preventive measures prevent eclampsia."

Dr. Eden quotes Prof. Couvelaire as saying that eclampsia has almost disappeared at the Clinique Baudelocque, Paris, and that he attributes this to the fact that the midwives are compelled to carry out regular examinations of the urine.

Mechanical Accidents of Labour.—Most catastrophes such as ruptured uterus and obstructed labour are the result of malpresentation of the child or bony deformity of the mother; their shadow is plainly visible during pregnancy to all who study prenatal diagnosis, and their successful treatment is one of the greatest achievements of preventive medicine.

No pregnant woman, primipara or multipara, should be submitted to the risks of labour without a careful consideration of her pelvis in relation to the size, lie, and presentation of the child; such routine examination, which is comparatively simple, will differentiate all pregnant women into three groups: (1) Grossly abnormal, major degrees of pelvic contraction, uterine tumours, organic heart disease, severe albuminuria. (2) Doubtful, minor degrees of contraction, bad obstetric histories—e.g., stillbirths, ante- and post-partum hæmorrhages, &c. (3) Normal.

The first group clearly requires hospital treatment or the equivalent; the second demands special supervision during the later weeks of pregnancy; whilst the third (by far the largest group) may be left with safety to deliver themselves at home. Under such conditions dystocia will disappear, perforation and the use of the cranioclast will become rare and will only be carried out under surgical surroundings on dead babies or monsters, and the unjustifiable application of high forceps with its attendant morbidity and stillbirths will be replaced by induction of premature labour or formal and safe Cæsarean section.

Prodromata of Hæmorrhage. — Placenta prævia usually gives warnings (slight bleedings in the eighth month), occasionally, however, a solitary bleeding is rapidly fatal. The same may be said of accidental hæmorrhage if one excludes the concealed type, which is almost invariably acute in onset and but rarely associated with prodromata. The majority of these concealed bleedings are seen in multiparæ (82 per cent. of the late Gordon Ley's series), and are toxic in origin; 84 per cent. of cases are associated with albuminuria, but it has not yet been determined whether the appearance of albumin precedes the bleeding or is merely coincident with it. It is hoped that further research will reveal the source and nature of the toxin and facilitate the diagnosis of the initial stages of the disease. All that can be said at present is that the pale, flabby multipara of many pregnancies is a potential bleeder, and that the appearance of albumin is of special significance in such cases.

Intercurrent or Pre-existing Organic Disease.—The relationship of pregnancy to independent organic disease has not yet received the attention it deserves, although it is well known that the process of reproduction has a profound influence on many morbid states in which the pregnant uterus may become a serious menace to life. In heart disease, for example, pregnancy taxes the reserve power of the heart, labour entails a strain which may be immediately or more remotely fatal, and embolism or persistent cardiac debility may follow an apparently successful delivery. To many of these patients the pregnant uterus is not a physiological but a malignant tumour, and it is the object of preventive research to determine the circumstances in which it is advisable and advantageous (in effect, a live-saving measure) to terminate pregnancy and prevent future conception. Of the five cardiac deaths mentioned in this paper, four occurred in multiparæ with 3, 9, 10, and 15 previous pregnancies. It is not unreasonable to think that if Cæsarean section and sterilisation had been carried out during one of their former pregnancies, the lives of these women might have been greatly prolonged.

Prevention of Sepsis.—The anatomical surroundings of the birth canal make antisepsis difficult and asepsis impossible, and it has indeed been shown that organisms are present in the vagina and even uterus after normal labour and during an afebrile puerperium. As the deeper tissues and blood-stream are easily accessible through small lacerations or through the placental site, which always offers a large venous and lymphatic portal of entry, it is a matter for surprise that dangerous infection is not more common. The natural defences, which must be extraordinary, are quite adequate to deal with natural delivery in the absence of gross contamination, and it is well known that the born before arrival invariably does well if the labour is otherwise normal. Of 28 cases born before arrival at hospital recently it was noted that the clothes of all the patients were offensively dirty, and that no personal preparation of any kind (skin, bowels, &c.) had been made: Fourteen women were delivered on arrival at the receiving room before any cleansing was possible; seven children were born in the street (in two cases the mother separated the child herself and walked a considerable distance to the hospital); three births took place in the ambulance, three in taxicabs, and one in a cookshop. In spite of these septic external surroundings every one of these women did well and the puerperium was afebrile in each case.

These results indicate that if labour is terminated naturally and without interference the external surroundings are relatively unimportant and the chances of auto-infection remote. The possibility of auto-infection cannot be denied, for it appears to be the only explanation of certain cases, but apart from these rare exceptions, puerperal fever is the result of infection from without.

One simple vaginal examination, if carelessly performed (with or without gloves), may carry virulent organisms from the ano-perineal skin with disastrous results. Repeated examinations are always risky, however careful one may be, and the risk increases with the amount of interference, from the application of forceps and versions to the manual removal of adherent placentæ, which is perhaps the most dangerous operation in ordinary midwifery.

Examination during pregnancy and just before term is not only perfectly safe, but will reveal most cases in which interference is likely to be required, so that suitable preparations can be made at home or the patient transferred (before labour) to hospital. In either case obstetric operations can be carried out deliberately, with surgical technique, proper assistance and equipment, and consequently with a minimum of risk of infection. The practice of pre-natal care will undoubtedly reduce the incidence of puerperal infection by limiting the number of obstetric operations undertaken as emergencies in patients' own homes, for it is these emergency conditions which are chiefly responsible for the development of puerperal sepsis.

Conclusions.

1. The majority of maternal deaths in childbirth are preventable by modern prenatal methods.

2. The majority of pregnant women receive no prenatal examination, and are therefore deprived of the advantages of modern treatment.

THE DIATHERMY TREATMENT OF GONORRHŒA IN WOMEN.

BY A. E. MILNER, M.R.C.S.,
PHYSICIAN IN CHARGE OF RADIOLOGICAL AND ELECTRICAL DEPARTMENTS, DERBYSHIRE ROYAL INFIRMARY, AND CHILDREN'S HOSPITAL, DERBY; MAJOR, R.A.M.C. (RET.);

AND

A. K. MACLACHLAN, M.B., CH.B. EDIN.,
SURGEON IN CHARGE, VENEREAL DISEASES DEPARTMENT, DERBYSHIRE ROYAL INFIRMARY.

IT has long been recognised that the treatment of gonorrhœa in women is very difficult to carry out successfully, and that the results are far from satisfactory; the fact that the gonococcus can spread by the vagina to the uterus and Fallopian tubes, and produce a general infection, renders the disease more difficult to cure in the female than in the male. Metastatic gonorrhœa occurs equally in both male and female, but the infected parts in the female are so difficult of access that local treatment is, in the majority of metastatic cases, only palliative; consequently the infected joints, &c., are not so easily treated as in the male, where the local condition can be successfully dealt with.

The usual condition found on examining a female with acute gonorrhœa is that there is a discharge from the urethra and cervix, and that the latter is eroded to a greater or less extent. The discharge from both contains pus and gonococci. From the os uteri the discharge varies; at first purulent, it later tends to become muco-purulent and ropy. It is in this condition that one sees most of the cases, and in the subacute or chronic stages, when the detection of the gonococcus is very difficult. If an acute case, the treatment of the urethra by lavage with sounds and urethroscopic treatment to follow will usually clear up the condition, but at the cervix uteri the latter is very persistent; treatment with the various medicated packs and tampons apparently produces little result, and the condition goes on until the chronic stage is reached, this state of affairs occurring even in cases restricted to bed.

Limits of Temperature Favouring Growth of Gonococci.

The hopelessness of the condition generally, and the fact that we had treated some cases of gonorrhœal arthritis with marked success, made us reason that something might be done in the actual treatment of the local condition with diathermy. It appeared obvious that as heat kills the gonococcus easily in culture, it only requires sufficient heat to kill it in the tissues; as diathermy would produce heat to the necessary extent, the idea would be to heat the cervix to such a temperature as would destroy the germs without burning the cervix. Georges Luys states that in culture the gonococcus can grow between 32° and 38° C., and that six hours at 40° will kill it. Below 30° C. colonies show no growth and tend to die at 18° C. Auguste Lumière and Jean Chrevotier, however, showed by their experiments that the gonococcus was even more resistant to cold.

Experiments carried out at the Military Hospital, Rochester Row, demonstrated that half an hour at 104° F. (40° C.) is a lethal dose for the organism. There is much discrepancy in these results. From our observations in the treatment of gonorrhœa by diathermy we conclude that a minimum temperature of 104° F. is necessary, and if that temperature is not exceeded it must be maintained for about an hour. These conclusions were arrived at in the treatment of men, in which cases the intra-urethral temperature of both the anterior and posterior urethra was taken every five to ten minutes, and in cases in which gonococci disappeared and were cured the temperature of every part of the urethra was not on an average maintained at 104° F. for longer than one hour.

Much higher temperatures can be attained and maintained in the female organs, from the fundus of the uterus to the urethra and external genitals, than in the male urethra. Gonorrhœa is easier to treat by diathermy in the female than in the male on this account, when the disease is confined respectively to these parts.

Technique.

In order to follow the technique of the treatment it is necessary to understand the physical properties of diathermy, and to dissociate it entirely from conducted and radiated heat. The tissues are very bad conductors of heat; for this reason it would be impossible by conducted heat to maintain the temperature necessary to effect a cure in the submucous tissues which have been penetrated by gonococci without burning severely the superficial columnar epithelium. By diathermy the superficial and deep parts can be equally heated; for it is penetrating, it passes through and through from one electrode to another, and is therefore ideal for the purpose. The amount of heat generated and maintained in any part under treatment does not entirely depend on the amount of current used, but on several other factors, one of the most important being the vascularity of the part. The more vascular the part the quicker the heat is carried away. The part of the body between the diathermy electrodes may be compared to the furnace of a radiator system.

The tissues are raised in temperature, and the fluid passing through the heated tissues is constantly carrying away heat, thereby reducing the temperature between the electrodes, and raising the general temperature of the body. It will be realised that any technique that retards the flow of blood through the part treated will raise the temperature of the part; this may be done by pressure of the electrodes, or compression of the vessels above or below the electrodes. The size of the active electrode exerts a powerful effect on the local temperature.

The two electrodes used in the treatment are of different sizes, the larger being the indifferent, while the smaller is the active electrode; the smaller the active electrode the greater is the concentration of heat around it. By reduction of the size of the active electrode a stage is finally arrived at when coagulation of the tissues takes place around it. The diathermy then becomes surgical. (For physical qualities of the current see THE LANCET, 1922, ii., 1316.) We have made various alterations in the shape and measurements of the active electrode; a cylindrical electrode three-quarters of an inch long and one-eighth of an inch in diameter, with rounded end, will, we think, be found the most convenient active electrode to use when the disease is a gonorrhœal cervicitis and endometritis. The circular discs should vary in size; the largest size that can be introduced through the speculum should be used. The larger the active electrode the better control can be kept on the temperature of the cervix and uterus, and the less likelihood is there of burning the mucous membrane.

Treatment of Gonorrhœal Endometritis, &c.

Presuming the case to be one of gonorrhœal endometritis, cervicitis, and urethritis, the treatment is carried out in the following manner. The patient having already been douched and placed on the couch in the lithotomy position, the indifferent electrode measuring 20 × 10 cm. is wrapped in a thick pad saturated in hot saline solution, and fixed by means of a binder on the abdomen as near to the pubes as possible. The cervix, os uteri, and urethra are cleansed with swabs. As large a speculum as possible is now introduced; in multiparæ a Haig Fergusson has generally been used, but in nulliparæ a Cusco has been found convenient.

The active electrode is screwed on to the holder and passed down the speculum; the stem of the active electrode is introduced into the os uteri with care, and the circular disc is then pressed gently against the cervix. Before the current is applied the speculum is slightly withdrawn to avoid contact with the active electrode. No overlapping of the vaginal wall should take place, the circular disc of the active electrode being kept in view throughout the treatment. The current is gradually increased, the temperature which it is desired to maintain is 107° F. It is, unfortunately, impossible to lay down any hard-and-fast rule as to the amount of current to be used; this will depend on the factors already discussed. All that can be said as a guide is that the amount of current usually necessary will vary from ¾ to 1 ampère.

The sensation of heat felt by the patient is not a good guide, as from our experience of these cases the cervix is peculiarly insensitive to heat; a superficial burn may occur without the patient suffering any discomfort. The temperature of the os was taken before the treatment commenced and was found to be on the average 99·2° F. The temperature after treatment of five to ten minutes varied from 102° to 112° F., and the difficulty of getting a correct temperature during the operation became evident.

We have now designed a combined active electrode and thermometer, which it is expected will give a constant indication of the temperature of the heated part. It would be advisable for those without experience of this operation to take the intra-uterine temperature every five minutes. Although a superficial burn of the cervix heals readily, it must be borne in mind that future treatment is held in abeyance until the part is normal again. The ordinary clinical thermometer must register within half a minute, and must be introduced into the os very quickly if the correct rise is to be registered, as the part is so vascular that the temperature drops to normal very rapidly when the current is cut off.

Treatment of Gonorrhœal Urethritis.

To treat gonorrhœal urethritis the indifferent electrode is drawn well down to the pubes; after lavage and swabbing of the urethra an active electrode which consists of a cylindrical metal rod five-eighths of an inch in diameter and of convenient length is introduced to the extent of 2½ inches into the vagina and pressed in an upward direction against the vestibule and urethra. More current will be required than for the treatment of the cervix—usually about 1½ ampères is sufficient to maintain the intra-urethral temperature at 106° F. The treatment is given for ten minutes and repeated five or six times when a cure should be effected. Smears should be taken the day after each treatment. No diathermy electrode should be introduced into the urethra on any account; the necessary lethal temperature can be attained with ease without this expedient, and all chance of a burn of the urethra avoided.

As in the case of the urethra, the duration of treatment to the cervix and uterus should be for ten minutes, provided that the temperature is maintained throughout at an average of 107° F. The results of diathermy are marked; the cervical erosion heals rapidly, the discharge becomes less, and gonococci gradually disappear from the smears. With a continuation of treatment the muco-purulent ropy discharge disappears, and quite clear mucous secretion, without any gonococci in either smear or culture, is then left. Some of our cases were treated in hospital and others as out-patients; they did equally well. It is not necessary to admit cases unless they get burnt.

Diathermy Burns.

It may be necessary to explain that the burn which has been mentioned several times in the course of these observations differs entirely from an X ray burn, or the burn which originates from the electrode of a galvanic battery. The latter are sometimes most difficult to cure. Most surgeons are now familiar with the wound caused by surgical diathermy. The burn which has occurred in some of the cases is a very superficial surgical diathermy coagulation, and there has been no difficulty, in spite of the previous infection, in obtaining complete healing. We strongly advocate team work in this treatment. The technique of diathermy can only be acquired by long practice, while the selection of cases suitable for treatment, their observation, general treatment, and the verdict as to establishment of cure, are matters best dealt with by an expert in venereal diseases.

Reviews and Notices of Books.

THE MEDICAL PROFESSION IN INDIA.

By Major-General Sir PATRICK HEHIR, K.C.I.E., C.B., C.M.G., I.M.S. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 139. 7*s.* 6*d.*

Patrick Hehir began his medical study in the Calcutta Medical College and finished it in Edinburgh and at Guy's Hospital. He spent the greater part of his active life in India, filling every sort of medical appointment in military life and many in civil life, including lecturing on various subjects, health officer to a large municipality, general practitioner, and consulting physician. Since his right to speak with knowledge on the position of medicine in India is combined with discernment and a rare sense of values, his book will appeal to all who take an interest in the medical services of India or in the advancement of medicine in that great country.

The author regards the present situation as critical, for the Indian Medical Service has lost its attraction for young graduates of the home medical schools, while the deficiencies in Indian medical education have not yet been made good. The entire environment of the medical student in the United Kingdom is more salutary and invigorating than it is in the Indian colleges where the student is not taught from nursery days onwards how to make things for himself and where written examinations loom very large. While there are probably not more than a few dozen Indians with the qualifications necessary to fill professorial chairs, there were until lately hundreds of officers of the I.M.S. qualified to do so. For this reason no exception can be taken to Rule 12 of the Devolution Scheme under which the India Office has reserved 305 civil posts for officers of the I.M.S., 240 under local governments, and 65 directly under the Government of India. Medical education in India has its good points, but it is gravely behind in the ancillary subjects—pharmacology, physiology, bacteriology—and training in midwifery cannot be compared with that at home. There are no fever hospitals or hospitals for special regions, or for skin diseases, and, most surprising of all, there are no dental schools or hospitals whatever in the country.

This is the base of the position on which Sir Patrick Hehir writes his book. He gives a bird's-eye view of medical education in India, a business-like account of the Government medical services, and a description of the independent medical profession in India which is highly challenging. On the British basis of one doctor to every 1100 persons, some 250,000 independent practitioners could be utilised in India, whereas, when the Medical Registration Act came into operation in 1913, as far as could then be ascertained there were about 1770 independent medical practitioners holding registrable qualifications. Sir Patrick Hehir marvels at the small recognition by Indian philanthropists of the needs of medicine and hopes to see some of the great wealth of India diverted in the direction of more hospitals and medical schools. He will not have it that officers of the I.M.S. have been encroaching on Indian private practitioners. Everything, he says, points to the reverse, but he would like to see the house appointments at college hospitals thrown open to the successful students of the year irrespective of whether they intend to enter Government service. The Indian Government is the only civilised government in the world which provides for the medical and surgical wants of the entire population and the education of practically the whole medical profession in Western medicine; the time has come for the people to do things for themselves.

A chapter on public health work in India makes it clear that the sanitary work of the Indian army has been one of the best parts of our administration. Sir Patrick Hehir would make it possible for natives of India to obtain a diploma in public health and instruction in tropical hygiene without recourse to the United Kingdom. The unpopularity of the public health department with I.M.S. officers owes its origin to the drudgery of their life, the absence of executive powers, and of scope for genuine ability. But although the hygienic conscience of large towns is awaking, Western sanitation has not yet been grafted into the routine life of the people, and no preventive measures will succeed until the coöperation of the people has been obtained. The unparalleled apathy of the native Indian in face of plagues and famines still remains.

In his concluding chapters Sir Patrick Hehir deals with the Oriental systems of medicine and with the medical work of women in India. He notes the increasing tendency for the women of India to take up medicine as a profession, although at present there are no Government appointments for women doctors and prospects in private practice are not alluring. There is evidence of thought and applied knowledge on every page of this book which makes it an indispensable work of reference for Indian medical study and practice.

SURGICAL DISEASES.

The Pathological Physiology of Surgical Diseases. By Prof. Dr. FRANZ ROST. Translated by STANLEY P. REIMAN, M.D., Chief of Pathological Department of the Lakenau Hospital, and Assistant Professor of Experimental Pathology, University of Pennsylvania. London: Stanley Phillips. Philadelphia: P. Blakiston's Son and Co. Pp. 535. 30*s*.

THIS book gives an account of the normal physiology and the pathological functioning of the different systems of the body when they have been damaged by injury or disease. It is a good compilation ably presented. The author says that the object of his book is to train the student "intellectually" as well as "mechanically" in the art of surgery. This is the accepted modern view of surgical education and the object of the successful attempts to introduce the physiologist and anatomist to the wards. The laborious task of translation has been well done. The book is too good to have a title made up of such a curious combination of contradictory terms.

OPERATIVE SURGERY.

Chirurgie de la tête et du cou. Précis de technique opératoire. Sixth edition. By CH. LENORMANT and PIERRE BROCQ. Prosecteurs de la Faculté de Médecine de Paris. Paris: Masson et Cie. 1923. Pp. 338. Fr.12.

THIS is a précis of operative surgery intended both for students and for medical men in general practice; the latter, according to the preface, should be able to perform any of the operations described in the book. We should imagine that few general practitioners in this country would care to attempt such formidable operations as removal of the upper jaw or the exposure of the pituitary fossa. Many who would have the necessary skill would be unable to use it with advantage in such unusual circumstances. The book is more likely to interest English operating surgeons, who will find in it succinct descriptions of a number of operations very rarely performed in this country, while they will be astonished to find how little known in France are some of our procedures. While several routes by which access can be gained to naso-pharyngeal polypi are described in some detail, there is only one thorough description of an operation for cleft palate, a modification of what in this country is known as Langenbeck's operation; no mention is made of Lane's, or any other flap operation, or of Brophy's procedure. Again, the only route of access to the pituitary described is a trans-sphenoidal one, involving turning down the nose; Horsley's cerebral route is dismissed in a few words as being difficult and dangerous, and Frazier's operation is not even considered.

Other striking divergences from English practice could be quoted, but enough has been said to indicate that readers of this little book will find it stimulating by providing an unusual point of view, although they would probably think it necessary to consult a larger text-book before embarking on an operation which they had only seen described in précis form, with but little reference to the difficulties, dangers, and complications. The book is well printed and lavishly illustrated.

PROGNOSIS OF INTERNAL DISEASES.

By HENRY L. ELSNER, M.D., LL.D., Professor of Medicine, College of Medicine, Syracuse University. London and New York: D. Appleton and Co. 1923. Pp. 1276.

THIS is a valuable book. Not only does the author discuss the prognosis of each disease, but he has been at pains to examine the prognostic importance of the chief complications and sequelæ in each case. In many cases he quotes valuable statistics as to the incidence of such complications, and at the end of each section the well-selected bibliography will be found of value by those anxious to read more deeply into any particular subject. Many laboratory tests are discussed, the utility of each from the prognostic point of view being carefully considered. It may, in fact, be said that at a time when medical text-books are multiplying with bewildering rapidity Prof. Elsner has produced a volume whose originality gives it an especial interest.

HEPATIC AMŒBIASIS.

Les Hépatites Amibiennes: Autochtones et Coloniales et Leur Traitement. By F. FRANÇON and J. HUTINEL, with a Preface by Prof. CHAUFFARD. Paris: Gauthier-Villars et Cie. 1923. Pp. 130.

HEPATIC amœbiasis in its manifold clinical guises is always a subject of very great interest to the physician in the tropics, and is, moreover, one with which the general practitioner, and even the specialist, in non-tropical countries is apt to be unfamiliar. This brochure by two distinguished French clinicians who gained their experiences of amœbic hepatitis and liver abscess during the war, is opportune. The diagnosis, ætiology, and pathology of these conditions are discussed with full references to the main contributions on the subject. The pleuro-pulmonary complications of liver abscess are admirably described, and recent experience has fully demonstrated the great value of the recognition of the true significance of signs at the right base. It is unfortunate that the authors should often convey the impression of attaching too great importance to the views of authorities quoted while relying too little upon the results of their own experience. A very full bibliography of 243 references is attached.

PSYCHOLOGY.

Recent Psychology and the Christian Religion. By CYRIL E. HUDSON, M.A., Assistant Curate, S. Mary Abbots, Kensington. London: George Allen and Unwin. 1923. Pp. 121. 3*s*. 6*d*.

THIS writer shows more than a literary knowledge of the first part of his subject and is to be congratulated on his sympathetic understanding. His theme is the relation of psycho-analytical observation and theory to Christian belief, and in his frank consideration he only once seriously departs from a correct statement of the position. That is when he attributes to the "Freudian school" the belief that "all human conduct, all human ideas, philosophies, religions, ideals, are the product of unconscious sexuality," a frequently repeated grotesquerie which has been dealt with by Freud in his "Introductory Lectures." A similar failure to go to original sources is indicated on p. 104, where a casual footnote reveals that Mr. Hudson has accepted a newspaper version of Prof. Sherrington's address to the British Association which ascribed to him a view of the mechanical interpretation of mind directly opposed to that which he really expressed. One feels compelled to point out these blemishes because they are not in harmony wth the rest of the book. The chapter on psychoanalysis and sin is, if one may be pardoned the emphasis, a remarkably honest presentation of psychoanalytical methods, difficulties, and results. In discussing free will the author is surely swayed by a primitive instinct when he rejects McDougall's sole justification of punishment of the wrong-doer—the hope that it may "modify his nature for the better"—and says, "This position seems to make *blame* or *censure* meaningless"; if blame or censure has no modifying influence it certainly is meaningless, except as a mild gratification of the desire for retribution.

As seems inevitable in a discussion of first principles, the argument of the book will succeed or not according to the temperament and "complexes" of the reader. In those matters—and they are vital—in which he differs from "the psychologist who is also a thoroughgoing evolutionist," Mr. Hudson is scrupulously fair in presenting the views of the other side: one wishes that all controversialists were like him.

Evolution of the Conscious Faculties. By J. VARENDONCK, D.Litt., D.Sc. London: George Allen and Unwin. 1923. Pp. 260. 10*s.* 6*d.*

THIS is a continuation of the theme of Dr. Varendonck's "Psychology of Daydreams." Formerly he showed how practised introspection had enabled him to trace his own pre-conscious thoughts and to deduce certain tendencies operative just below the level of consciousness. In the present work he distinguishes between reduplicative and synthetic memory; even in mankind the former need not be associated with consciousness, and it determines the automatic and reflex behaviour characteristic of lower stages of evolution; but the necessity for choice determines repression of a certain amount of reduplicative memory and demands selection and synthesis to guide the reaction to external excitations. In this way the conscious faculties of man, in whom choice is continuous, develop from those of the animal, which only from time to time departs from reduplicative action.

In spite of an involved style, Dr. Varendonck produces in his readers a sense of the reality of his subject. His work is now coming to form a useful link between the intellectualist psychology and the psychology that studies processes which take place at the lower and more primitive levels of the mind.

LABORATORY DIAGNOSIS.

Traité de pathologie médicale et de thérapeutique appliquée. Diagnostics de laboratoire. II. Tumeurs, par M. P. MASSON, Professeur d'Anatomie Pathologique à la Faculté de Strasbourg. Paris: A. Maloine et Fils. 1923. Pp. 797. Fr.50.

THIS volume is the twenty-seventh of the whole series and the second dealing with laboratory diagnosis; if all the other volumes of the series are up to the standard of this one they deserve to be more widely known in this country. This particular volume is designed for the use of the practising morbid histologist, and consequently, in addition to a general theoretical discussion of the nature and growth of tumours, both granulomatous and neoplastic, and a full description of tumours of all sorts, it comprises an extensive and useful section on histological technique.

The "Etude Théorique des Tumeurs" is neither more nor less useful than such discussions usually are. The "Etude Concrète," however, is excellent; no class of tumours seems to have escaped the notice of the author, and of all of them his descriptions are admirably clear. What is more, these descriptions are accompanied by illustrations constituting the most valuable feature of the book; they are numerous, and the author has wisely not included a single microphotograph. In hardly any instance could the veriest tyro fail to identify a section from its appropriate illustration—and how seldom can this be said of microphotographs.

Morbid histology in this country, when it derives from abroad at all, tends to do so from German, to the exclusion of other, sources. Perusal of this book calls attention to a number of interesting points not usually stressed in this country; for instance, the form of chronic mastitis, called by the author "Maladie de Reclus," occurring in young women, and illustrated by him in Fig. 49, is one which, though occasionally met with, has escaped the notice of most English writers; most pathologists will readily recognise it from the illustration, although some might disagree with the author's description of it as a "hyperplasie myo-epithéliale." Volkmann's view of the endothelial nature of the mixed tumour of the parotid is only mentioned that the author may insist on its untenability, and it is quite time that in this country the name "endothelioma" ceased to be mentioned in this connexion. On myeloid and melanotic "sarcomata" also the author holds views well worth the consideration of English workers.

And all pathologists in this country will greet with applause the author's concluding passage: "L'histodiagnostic est un acte médical. C'est une consultation médicale dans laquelle la responsibilité de l'histologiste est gravement engagée, d'autant plus que son expertise est demandée en général en dernier ressort et commande la thérapeutique. Médecin, l'histologiste doit être payé en raison des services qu'il rend."

LIFE OF SIR T. P. ANDERSON STUART, M.D.

By WILLIAM EPPS, Secretary of the Royal Prince Alfred Hospital, Sydney. Sydney: Angus and Robertson, Ltd. 1922. Pp. 177.

THIS interesting book is partly autobiographical and partly matter compiled by Mr. Epps from documentary evidence supplied by Stuart together with personal recollections of the subject of the memoir. As Mr. Epps says himself, the book, owing to circumstances of publication, had to be cut down by about one-half and this has somewhat affected its balance, continuity, and smoothness, but the admirable introduction gives an excellent sketch of Stuart's many-sided character and activities, which sketch can be supplemented at the reader's will by reference to the main body of the work.

Thomas Peter Anderson Stuart was born in Dumfries in the year 1856, the son of Alexander Stuart and Jane Anderson his wife. He was educated at the Dumfries Academy and at the age of 14 was apprenticed to a chemist and druggist. After two years he decided to enter the medical profession, and after passing the preliminary examination during a further 18 months went to Wolfenbuttel in Germany, where he acquired a fluent knowledge of French and German. In November, 1875, he began his university career at Edinburgh, and his memories of those days and his recollections of Lister, W. Turner, and T. Keith are well worth reading. We think that his memory must have betrayed him in one small point and that is where he says (p. 29) that at this date "I saw the first young lady without a crinoline, which had been universal up to this time." He took his M.B. in 1880 and passed the first M.R.C.S. and primary F.R.C.S. Eng. examinations, obtaining in the latter 24 marks out of a possible 25. He then accepted the post of demonstrator to Prof. Rutherford, carrying with it that of assistant professor of physiology. The agreement between them, which Mr. Epps gives in full, is a curious and interesting document. With regard to fees for lectures, the Edinburgh professors in those days collected by themselves—i.e., they sold the class tickets at the door of the lecture room, "taking the money with their own hands and giving change." Stuart stigmatises this custom as "rather degrading," but whether this be so or not the custom was simply a survival of mediæval university practice, when learned doctors used to employ a couple of students to negotiate with other students as to how much each was to pay. Rashdall (Universities of Europe in the Middle Ages) gives a delightful quotation from the works of Odofredus, an eminent jurist of Bologna, announcing at the termination of one course of lectures that next year he would give no afternoon lectures because the scholars were not good paymasters, "quia volunt scire, sed nolunt solvere." The same custom of payment obtained at Paris and Oxford.

Then came the great turning point in Stuart's life, for in 1882 the Government agreed to find the money for the provision of a medical school in the University of Sydney and applications were invited for the chair of anatomy and physiology. Various competent bodies were asked to nominate a professor, and the University of Edinburgh, the Royal College of Surgeons of Edinburgh, the College of Physicians in Glasgow, and the Royal College of Surgeons of England were asked for their views. All these bodies unanimously nominated Anderson Stuart. He arrived in Sydney in 1883 and found that the medical school consisted of "a little four-roomed cottage with walls about half-way up." How the school grew both in numbers and in the various buildings from this small beginning—4 students in 1883 and 857 in 1919, while the progress of the buildings is shown by the two photographs opposite pp. 52 and 114 respectively—must be read in Mr. Epps's striking narrative. This was Stuart's life work; to this end he organised, cajoled, and drove anyone who by reason of learning, interest, or money could further his heart's desire. And all the time he was teaching as only a master could teach, besides filling such important posts as that of Government medical adviser, President of the Board of Health, and chairman of the Board of the Royal Prince Alfred Hospital. Stuart died in 1920 of an internal malignant growth, of which he first became aware in 1919, and he passed the last year of his life under sentence of death with the same courage which he had always shown during his working years. A great man to whom anyone seeing the medical school of the University of Sydney may well apply the well-known epitaph of Wren.

A GREEN OLD AGE.

By Prof. A. LACASSAIGNE. Translated by HERBERT WILSON from the second French edition. London: John Bale, Sons, and Danielsson, Ltd. 1923. Pp. 321. 15*s*.

THE increase in the expectation of life which has become so marked during the last 50 years is apparently responsible for a corresponding increase in the number of books upon old age and what may be called its management. Prof. Lacassaigne's book on the subject is one of the best which we have seen. He has himself arrived at an age which even in these days may be called advanced, for he was born in 1843; he is a medical man and professor of legal medicine in the Faculty of Medicine at Lyons, is learned and widely read. We know on the best authority that the "cruda viridisque senectus" is the attribute of a god,[1] but a study of Prof. Lacassaigne's book will enable mere mortals, if not to attain old age, at least to enjoy the fresh and youthful senescence spoken of by Virgil. It is full of sound advice and the advice is accompanied by a wealth of illustration drawn from literature both ancient and modern, from artists, and from examples of those who have attained old age and found it green. Those whose years are declining will learn if they digest the principles laid down by Prof. Lacassaigne how to temper the sadness of Ecclesiastes' picture of old age by remembering Nestor, who "yielded not to grievous old age."

JOURNALS.

IN the MILITARY SURGEON for August there is a paper on Chemical Warfare and its Relation to the Medical Department by Lieut.-Colonel H. L. Gilchrist, Medical Corps, U.S. Army, who was, in the war, medical director of the Chemical Warfare Service, and afterwards head of the American Typhus Expedition to Poland. In the war we used to speak of "gas," but in future shall, he thinks, talk of "chemical agents." As these are generally heavier than air, they settle into shell-holes and dug-outs, making them dangerous, so positions on high ground will be more coveted than ever. The best protection is a gas-mask, but even a moistened handkerchief, wetted (it may have to be) with urine, is often of great value. Alkaline applications are recommended, ammonia for inhalation, weak (2 per cent.) bicarbonate of soda solution for the eyes, lime water and stronger soda solutions for the skin or to be taken by the mouth. Orderlies should be specially trained in first-aid for chemical casualties; they themselves at such times wearing always protective masks, gloves, and clothing. Every field ambulance should carry, for each person it is equipped to deal with, one litre bottle of oxygen, to be put on the stretcher with him if gassed, between his legs, its outflow being led by a rubber tube into his mouth or nose. Steam disinfection best gets chemical agents out of clothing; and shower baths, to free patients from mustard gas, should be pushed well forward, even in a battle to within five miles of the front.

Lieut.-Colonel E. L. Ruffner has a paper on the Citizens' Military Training Camp, which seems to be a very interesting effort of the Government to encourage the physical development of the people. The camp is in summer, it lasts a month, and is free to any young man over 16 and physically fit. Those who come get systematic physical training, education in discipline, order, and neatness, swimming, baseball, and other games, and are vaccinated and inoculated against typhoid, all for nothing. Colonel Ruffner was himself on the staff of such a camp in 1922; there were 2582 men in his, and the average gain in weight shown was 2½ lb. All were medically inspected on arrival, and only two serious cases were sent to hospital during the month. The State paid for their holiday and their teaching, just to make them better citizens, requiring of them no contract of service!—Dr. H. Lilienthal figures a simple and ingenious method for holding Carrel's tubes steady in a superficial wound. The tubes are bent at the ends, like capital J's, and the curved portions are worked into paraffined gauze which does not stick to the granulations, and out of the gauze the tubes do not tend to slip. This simple expedient was devised by a nurse, Miss Hervey, who served with the British Army in France.

An interesting paper shows that the disease called tularæmia is a *Bacterium tularense* septicæmia. It was first recognised in Tulare County, California, in 1912, by McCoy and Chapin, when investigating a novel epidemic amongst ground squirrels. It is found also in rabbits, and may be inoculated into guinea-pigs. It causes patches of necrosis on the livers of the rabbits, and cooks and butchers who handle these livers become infected if they have abrasions on their hands. There is inflammation at the point of entry, adenitis is associated, prostation and fever follow, with slow recovery after a month or two. Thirteen days after invasion the blood serum, in a dilution of 1 in 100, agglutinates cultures of *B. tularense*. The bacterium does not grow on ordinary agar, and only scantily on blood-agar, but, it is found by Surgeon Edward Thomas, of the U.S. Public Health Service, who presents this paper, it will grow freely on a serum-agar, with glucose (1 per cent.) and cystine (0·1 per cent.), and this in original isolation or in subcultivations. This disease was first found on the Pacific Coast, but Surgeon Thomas has found it on the Atlantic Coast too, for, out of 914 rabbit livers, taken in the market of Washington, D.C., he found seven were infected.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 29, 1923.

THE COMING INSURANCE SETTLEMENT.

THERE remain but three months before the end of the year, when new conditions for medical service under the Insurance Acts will come into force, and although the final proposals have not been made or accepted a large measure of agreement has been reached by conversations between the Ministry of Health and the Insurance Acts Committee of the British Medical Association representing panel practitioners. The fixing of the capitation fee was left until substantial agreement had been reached in regard to the services to be rendered for that fee, and within the next day or two the actual proposal in shillings and pence will reach the Insurance Acts Committee in time for its meeting on Oct. 4th. The final proposals both as regards terms and conditions of service will then be sent down to the panel committees in order that their representatives may come to a final decision in annual conference on Oct. 18th. No commendation would be too great for the spirit in which these conversations have been carried on.

Setting aside the amount of the capitation fee, which is as yet speculative, many points in regard to the terms of service have been decided to the satisfaction of all parties. These include in general terms: the limitation of panel lists, the free choice of doctor, the procedure of the Medical Service Subcommittee, procedure in regard to excessive prescribing, the right of the practitioner to have a patient removed from his list, and the access of the regional medical officer to the doctor's premises. Agreement has not been reached in regard to the right of panel committees to initiate complaints. Unless this concession is granted without giving the approved societies further facilities on their side for raising complaints, the panel medical service prefers to leave matters as they are. The proposal of the panel service to formulate a schedule of services that are outside the doctors' contract has not been accepted, and is not to be pressed, although the Insurance Acts Committee believes that such a schedule would be useful to all parties. The panel service is firm in its refusal to accept liability to give an anæsthetic or provide the services of an anæsthetist in connexion with *any* operation performed by *any* medical practitioner, although ready to make substantial concession. It is on the medical certification rules that the panel service is most keenly disappointed, for its proposals for the drastic reduction of the number of forms have not been accepted; the Insurance Acts Committee still believes that a friendly talk would solve the difficulties. The Committee's suggestion is in brief that all forms should be on two pieces of paper and that practitioners should be given the option of having these forms bound in one or other of two ways: (1) a separate book for each kind of certificate, (2) a book to contain copies of each kind of form—the one to meet the needs of urban, the other of rural practice. On one other knotty point disagreement remains. The Ministry endorsed the suggestion of its Insurance Consultative Council that in view of the unrestricted right to transfer at any time, there was no longer justification for allowing practitioners to treat insured persons as private patients. While the Insurance Acts Committee recognises the possibility of abuse, it regards the solution of this problem by regulations as impossible, holding that professional honour and increased knowledge on the part of the insured person must still be relied upon. There are insured persons who insist on exercising their inherent right not to accept the benefits for which they have paid, or who insist on going to another panel practitioner for a second opinion without mentioning the fact. Panel practitioners are often called into consultation by each other, and if no fee could be offered all consultation work of this kind would be transferred to non-panel practitioners.

We have emphasised the remaining points of divergence, although the measure of agreement is the striking feature of the situation. The agreement is indeed much greater than would be supposed to be the case from a perusal of the presidential address at the annual conference of friendly societies, which we summarise on another page. Public utterances of protagonists, although worthy of study, need not be taken quite at their face value. As the Insurance Acts Committee points out in the last sentence of its last communication, the two departments—namely, conditions of service and rate of remuneration—are indissolubly related, and any satisfactory arrangement arrived at must include both. We have substantial cause to hope that with the spirit now prevailing an arrangement will be reached towards the end of next month which will ensure good value to the insured person and willing service from the panel doctor.

◆

THE CARE OF THE MENTALLY DEFICIENT.

THE annual report[1] of the Metropolitan Asylums Board is a recurrent reminder of the scope and variety of remedial work which this Board undertakes. To the London medical student who thinks of the M.A.B. hospital as synonymous with the treatment of scarlet fever and diphtheria, with a sprinkling of typhoid, it may be necessary to recall that the Metropolitan Poor Act, 1867, empowered the combined parishes of the metropolis to establish asylums for the reception and relief of the sick, insane, and infirm, or other classes of the poor, without limitation to any particular infirmity; and over and above its hospitals for the common infectious diseases, for small-pox, for venereal diseases, and for tuberculosis, the Board administers mental hospitals, with a total accommodation of 8800 beds and an industrial training colony for 2200 mental defectives. In these institutions the patients are classified from the higher grade of improvable patient in training at Darenth to the senile dements at Tooting Bec and the lower grade of imbecile child at Caterham and the Fountain Hospital, Tooting; the advantage of pooling the subnormal mental population of the metropolis has been amply justified by the increased efficiency achieved by classification. The average annual number of new admissions from the metropolis is just over 1500, and there are now more than 1600 patients received by agreement with provincial authorities under the Mental Deficiency Act of 1913, in spite of the fact that the war rendered this Act largely nugatory. Some minor rearrangements have been carried out during the year, including absorption of the special children's receiving home at Tooting Bec into the general accommodation of the hospital, and some adjustments at Leavesden and Caterham designed to reduce waiting lists and increase efficiency. All the patients at the Bridge Training Home, Witham, Essex, were transferred during the year to Darenth, where the industrial work has attained very large proportions. There is an output of over 20,000 envelopes weekly from the bookbinding shop, a weekly average of 112 new or remade mattresses from the upholstery shop, 400 pairs are dealt with weekly at the boot-making shop, while brush-, basket-, and mat-making are in full swing, and the tailoring shop is kept full up with orders. All this work is so important that we welcome the expansion of the annual report to its original size and form, in which a special section, edited by Dr. E. B. Sherlock, director of the Board's Mental Hospitals Service, is devoted to mental diseases.

---

[1] To be obtained from the office of the Board, Victoria Embankment, London, E.C. 4. 5s. Mental Diseases Section separately, 1s.

As a training ground for nurses the M.A.B. mental hospitals provide an immense scope. Dr. Sherlock contributes to the report a note on mental nursing which is of particular value at a time when the relation of general and special nursing is being so closely considered. Certain American States are now making it compulsory on nurses who accept registration from the State to have received some psychiatric training, and, under the auspices of the General Nursing Council, proposals on similar lines may eventually be made in Great Britain. General and mental nurses have already been placed on the same footing so far as this Council is concerned, and to gain admission both to the general and to the supplementary part of the Register, five years' training will be necessary, of which three must have been taken continuously in an approved hospital whether general or mental. The certificate of the Medico-Psychological Association is of great value to the special nurse, for it distinguishes in the third year between mental nursing and the nursing of mental defectives, albeit the whole period of training for the certificate must still be passed in one recognised institution. The Association is continuing at present to grant certificates, although after June, 1925, the examinations of the General Nursing Council will supply the only means of reaching the Register. Dr. Sherlock concludes his timely note with an inquiry into the respective value to mental nurses of experience and of the capacity to pass examinations, a query which he leaves for the moment unanswered. The Board's mental hospitals and training colony are also available for post-graduate medical study as they have been placed on the list of recognised institutions in connexion with diplomas in psychological medicine. This is also the case with the Royal Earlswood Institution at Redhill, which offers facilities for the scientific study of all classes of mental defectives; demonstrations and lectures are given periodically to post-graduate and other students from London medical schools, and the resident appointments should prove attractive to scientific workers willing to coöperate in the solution of the many problems still surrounding the ætiology, pathology, and treatment of mental deficiency.

Amongst the causes assigned in the Earlswood report for the mental deficiency of the 35 recent admissions are heredity, shock or indisposition of mother, prolonged labour or instrumental delivery in eight each; tuberculosis or tuberculous history in three; premature birth in two; and of the following—consanguinity of parents, fright, meningitis, convulsions, encephalitis lethargica, pituitary insufficiency—one example of each. Twenty-one, or 60 per cent., of those admitted in 1922 were under 14 years of age, but there is a large adult population accumulated during the 75 years of the institution's existence, and 16 are referred to as being over 65 years of age and four over 75. The inmates are drawn from varied social classes, 15 being classified as free cases, 19 as life payment cases, 168 as elections and part payment cases, and 20 as payment cases aided by public and local authorities under the Mental Deficiency Act. It is unfortunate that a technical difficulty has arisen in regard to the further admission of patients of the last-mentioned class, the Board of Control demanding as a condition of Treasury grants towards maintenance certain "contracts" which the Earlswood Board are unable to undertake. Details are given in the report as to the care, treatment, education, industrial training, and recreations of the inmates, the medical side of the work being in the hands of Dr. D. Hood, hon. consulting physician, and Dr. C. Caldecott, medical superintendent. The establishment of further institutions for defectives under the provisions of the Mental Deficiency Act will no doubt open careers for those desiring to specialise in this work. Moreover, there is at Earlswood a considerable scope for attaining experience in the management of diseases of children, especially of nervous type, which may be serviceable in ordinary practice.

DIFFERENTIAL ACTION OF X RAYS.

When a beam of X rays passes through the tissues it gives rise in them to reactions which vary in severity with the nature of the tissue traversed. This is generally referred to as the selective action of the rays; it is one of the few indisputable facts in radiotherapy and is the solid basis upon which that therapy rests. There is, however, another and scarcely less important aspect of the effects of these rays upon cell life, and that is whether a differential action exists. The question was put by Perthes as early as 1905 whether, in the absorption of the same quantity of soft and hard rays, the same physiological effects are produced. Since that date a good deal of evidence, mostly derived from clinical experience, has been brought forward by the French school of radiologists to show that in the case of the human skin differential action of this kind takes place. Their methods of measurement, however, lacked the precision which is necessary to settle such a question, and some years later the experiments of Friedrichs upon a variety of organisms led him to the view that no such action existed. In our present issue a series of experiments are described by Prof. S. Russ which seem to establish the position once more for a true differential action. It is maintained by the author that this proof depends entirely on the method which is used to measure the various doses of X rays in question. The customary method of measurement among physicists has been one based upon the ionising power of X rays, a method that has served them so well in the past that it is difficult to understand the long delay for its acceptance in medical radiology. Even so, however, the method has its pitfalls when accurate quantitative data are required and these are dealt with at some length by Prof. Russ. For the specification of X rays two quantities are essential—viz., their wave-length and their intensity. Spectrometer methods are now available for the former, but for the measurement of the intensity there is no unanimity at present. We understand, however, that a joint committee of the Physical and Rontgen Societies has been formed with the object of defining a standard of X ray intensity which shall eventually enjoy international sanction and usage. If the main feature of interest in a differential action of X rays lies in its relation to the technique of the therapeutic application of these rays, it has an important bearing on the general theory of the causation of the biological actions to which the rays give rise. So far the author has determined numerical ratios for only two varieties of tissue over a moderate range of the X ray spectrum. An extension of this class of observation, both in the range of the radiation and in variety of tissue should put us in a position to evaluate the physiological response in a more general sense than is possible at the present time.

◆

AYURVEDA AND UNANI.

IT is intriguing to think that the drug lore of the Eastern world has not yet been fully exploited in the interests of scientific medicine. The discovery of the healing value of opium and quinine has its parallel in the romantic search in tropical jungles for the rare chaulmoogra tree. One of the best-equipped laboratories in India—namely, that of the Calcutta School of Tropical Medicine—is now occupied with the investigation of indigenous drugs, and Major R. N. CHOPRA and his assistants are examining berberine and other reputed anti-malarial drugs, in the hope that some of the remedies used by the ancient Indian systems of medicine may prove cheaper and more efficient than those imported at great cost from Europe. At this point the indigenous systems have been deemed worthy of an exhaustive report by one of the largest provincial Governments in India, and we are able to publish this week in another column a summary by our special correspondent of the conclusions of a committee appointed in November, 1921, by the Madras Government. Able and interesting as this report is, we doubt whether it will advance the repute of the Ayurvedic and Unani systems of medicine. The memorandum by Dr. S. MURTI, secretary of the committee, removes the report from the ordinary criteria of reason by stating that every system of Hindu thought is at once philosophy, science, and religion, all in one and one in all. Dr. MURTI gets over the present lack of modern scientific equipment by premising that the old Hindu teachers, by improving their own internal organs of sense, could extend their range of perception to include the visualisation of the atom. Modern conceptions of catalyst, enzyme, and hormone have for him had their precursor in the mysterious humours of Ayurvedic theory.

It is sadly apparent that, if there is no more to be said for this system than Dr. MURTI has to say, modern medicine has little to hope for from its contribution. The truth appears to be, as Sir PATRICK HEHIR justly and moderately states in a monograph reviewed in our present issue, that Ayurvedic medicine has remained stationary since the Middle Ages, and that while the Unani system, with its Rhazes and its Avicenna, helped in the foundations of Western medicine it ceased to be affected by the advance of science after being carried to India by the Mohammedan invaders. Both systems have, in fact, undergone serious deterioration, for new religions were introduced, caste distinctions became more rigid, and the Brahmins, fearing to touch blood or diseased matter, left the study of medicine to the lower and illiterate castes; so that when the British founded medical schools and hospitals in India 120 years ago the native systems were in the last stage of decline. The more advanced Ayurveds now practise a hybrid combination of the Western and Oriental systems. Dr. M. C. COMAN, attached to the Medical College at Madras, failed to find marvellous properties in any drug not already known to Western medicine, and even on the plea of economy he found that the cost of maintaining an Ayurvedic dispensary was much the same as that of any other dispensaries. Dr. COMAN did, however, find a few drugs worthy of future study, including *Hydnocarpus inebrians*, potent in ameliorating the complications of leprosy, *Artemisia maritima*, a substitute for santonin, and *Boerhavia diffusa*, a good diuretic for anasarca. Sir PATRICK HEHIR demands a comprehensive investigation of native drugs and curative methods, asking for a more or less permanent committee, consisting of chemist, physiologist, pharmacologist, along with a native practitioner of high repute. His own feeling is that the attitude of indifference and hostility has been not altogether wise, for it has tended to the creation of a harmful class of quack and charlatan. The Hindu system could hardly have survived for over 2000 years, nor the Arabic system for many centuries, if they did nothing but harm, and the desire now becoming vocal on the part of Ayurvedic and Unani practitioners to bring their systems into more intimate relation with modern scientific medicine deserves recognition. We shall ourselves benefit by acquiring the useful parts of their knowledge.

Sir PATRICK HEHIR strikes a note of warning, for he does not believe that Western medicine has got as firm a hold on the people of India as many have supposed. The Medical Registration Act of 1916 neither included nor expressly excluded practitioners of Oriental systems, and he would solicit their coöperation in formulating curricula of education and in prescribing the courses of theoretical and practical training over some years before granting qualification to practise. Gradually the science of modern medicine could be introduced into the Oriental systems, which would then become instruments for conferring vast benefits on the people of India. There may be no other way in which adequate medical treatment will reach the masses of India in the immediate future.

Annotations.

"Ne quid nimis."

THE CENTENARY OF "THE LANCET."

ON Sunday, Oct. 5th, 1823, the first number of THE LANCET appeared, and in celebration of the event a special number of the journal will be issued on Oct. 6th, and a Centenary Dinner will be held in London on the evening of Thursday, Nov. 29th, at the Hotel Victoria, Northumberland-avenue, London, W.C., at 7.30 for 8 P.M. Sir Donald MacAlister, President of the General Medical Council, will take the chair, and will be supported by the Presidents of the Royal Society, the Royal Colleges of Physicians of London, Edinburgh, and Dublin, the Royal Colleges of Surgeons of England, Scotland, and in Ireland, the Chief Medical Officer of the Ministry of Health, the President of the British Medical Association, and the Presidents of the Royal Society of Medicine and of the Medical Society of London. The Minister of Health has signified his intention of being present, and it is hoped that a gathering representative of all the interests associated with the medical profession will meet on this occasion. Those who desire to be present should communicate at their early convenience with Mr. H. D. Gillies or Dr. J. H. W. Laing (hon. secs.) at 7, Portland-place, London, W. 1.

The charge for the dinner has been fixed at 15*s*., exclusive of wines, and if notice be given in advance endeavour will be made to arrange that friends who so desire shall sit together.

PRIMARY CARCINOMA OF THE THYMUS.

Dr. Victor C. Jacobson,[1] of the Peter Bent Brigham Hospital, Boston, who records an illustrative case, remarks that primary tumours of the thymus are uncommon, primary carcinoma, of which this case is an example, being exceedingly rare. The first diagnosis of carcinoma of the thymus seems to have been made by Bristowe in 1854. Only 2 cases have appeared in American literature, 13 have been recorded by French writers, all between the years 1890 and 1908, and 6 by English and German observers, or a total of 21 cases. Fourteen were males, 3 females, and in 4 the sex was not recorded. The age-incidence differs from that for epithelial growths in other organs. Altogether 15 patients were of the "cancer age," 6 were aged from 18 to 22. The relatively high percentage of thymic tumours in young persons is explained by the early evolution of the thymus as compared with other organs. In 3 of the recorded cases no metastases are mentioned. Lung metastases were reported in 4 cases, direct extension into overlying lung tissue was noted in 2 cases, in one of which the mediastinal lymph glands were involved. In one instance there was growth into the superior vena cava, and in two others the pericardium was affected. In only two instances in which nodules were present in the liver was a tumour found elsewhere than in the thorax. Dr. Jacobson's case occurred in a man aged 42, in whom the outstanding clinical features were the lack of local signs of thymus tumour and the predominance of symptoms referable to the destruction of several vertebræ. The symptoms were increasing pain and stiffness in the back and hips, and lower dorsal kyphosis. In spite of the large amount of lung tissue replaced by tumour the patient had little respiratory distress until shortly before death, which occurred after about eight months' illness. Although he also had acute appendicitis, all pain and tenderness in the appendix region were masked by the constant severe pain caused by the tumour in and about the vertebral column. The thymus tumour itself was comparatively small, and could not have caused much mechanical inconvenience. The lymph and blood-streams, however, were invaded early, the tumour being brought to the lungs by the pulmonary artery. In the lungs tumour cells gained entrance to the pulmonary veins and, reaching the systemic circulation, invaded the spine, liver, and suprarenals. The greatest interest from the pathological standpoint was the peculiar degenerative changes in the nucleus and cytoplasm of the tumour cells in the thymus and in the secondary growths.

THE WELFARE OF THE BLIND.

THE Blind Persons Act of 1920 imposes the duty on county and county borough councils to promote the welfare of blind persons ordinarily resident in their area. The fourth annual report of the Advisory Committee on the Welfare of the Blind records the progress now made. There are only four out of 145 local authorities who have not yet submitted schemes to the Ministry of Health for approval, and the majority of these schemes are now in operation. Their financing depends partly on the rates and partly on subsidies from the Ministry of Health, but the principle of making full use of voluntary agencies and the grant to them when necessary of financial assistance is maintained. This principle has been objected to by some theorists, but the fact remains that up to the present there has been no reduction of voluntary contributions to the funds of agencies for the blind. Out of a total of £75,000 paid by the Ministry of Health last year in respect of services provided for the welfare of the blind £33,000 went to workshops, £9000 to home workers, and £14,000 to home teaching. With regard to workshops for the blind the report states that workers in them may be grouped in four categories: (*a*) 60 per cent. are good workers, able to earn at trade-union rates 16*s.* a week in the case of men and 8*s.* a week in the case of women; (*b*) 8 per cent. are good workers but slow; (*c*) 28 per cent. are of low earning capacity capable of common work only; (*d*) 4 per cent. are devoid of any real earning capacity.

In view of the large proportion of low wage earners, the Committee recommends that there should be an efficiency and productivity test before any blind person is admitted to a workshop, and the Ministry of Health has given notice that from April 1st, 1924, it will not be prepared to recognise for grant purposes any blind person as a journeyman until satisfied that he has attained as high a standard in the quality, speed, and independence of his workmanship as is reasonably attainable by him. The problem of assisting home workers presents greater difficulties than that of assisting workshops. At the present time there are about 1000 recognised home workers, and for the time being the Committee recommends that earnings should be augmented at a flat rate not exceeding 10*s.* a week. A more important matter is the supply of teachers for home workers, and a good deal of attention has been paid to it. All home teachers, in order to earn the grant, must now pass the examination of the College of Teachers within two years from the date of their appointment. The first of these examinations was held last May at the School for the Blind, Swiss Cottage, when over 50 persons, all of them home teachers, presented themselves for examination. Besides these two classes of blind workers the Committee have approached the question how far it is possible for employment to be found for some of them in factories and workshops where ordinarily only seeing operatives are employed. In Germany it is said that as many as 450 blind persons are actually employed in ordinary factories and workshops. The report appeals to the employers of this country to interest themselves in this matter, and to grant facilities for testing the ability of blind persons to perform simple operations usually carried out by seeing workers.

The degree of blindness which qualifies for assistance under the Act is a matter needing more exact definition than it has yet had. There are a number of border-line cases who may have been encouraged for a number of years to regard themselves as blind, and the Committee favours the continuance of grants to these. On the other hand, there are a number of children in blind schools to-day, chiefly myopes and subjects of phlyctenular keratitis, who are weak-sighted but not blind. It is in the interests both of the country and of themselves that these children should be allowed to use the sight that they have under proper supervision, such as is given at the L.C.C. myope schools.

AUTO-PYO-THERAPY.

THE practice of auto-sero-therapy does not seem to be as popular as it was some years ago, and the results of the subcutaneous injection of a few c.cm. of a pleural effusion taken from the same patient have not been uniformly good. A treatment which bears at least a superficial resemblance to auto-sero-therapy has lately been advocated by Dr. Endre Makai,[1] head of a surgical children's hospital in Budapest. For more than a year he has been treating every case of localised suppuration by auto-pyo-therapy, dispensing altogether with a knife, and adopting a procedure the technique of which is perfectly simple. The pus in an abscess is aspirated, and 1 c.cm. is immediately injected subcutaneously, this procedure being repeated every fifth day as often as necessary. Several such injections have been given in each of more than a hundred cases, the ages of the patients, most of whom were children, ranging from infancy to 40. In the case of closed, cold, tuberculous abscesses, the subcutaneous injection of 1 to 10 c.cm. of the pus never gave rise to a troublesome general reaction such as fever or general malaise. On the contrary, there was often a dramatic improvement with gain of weight. At first there was no local reaction. As the injections were repeated, more and more definite areas of painless infiltration would appear. The microscopic changes in such areas were characteristic of tuberculosis, but tubercle bacilli were not demonstrable, and the infiltration always disappeared automatically. After two to eight injections, during which the pus steadily became more fluid and transparent, the abscesses dwindled or disappeared completely. Curiously enough, the subcutaneous injection of another patient's cold abscess into a person suffering from the same complaint had no effect. Good results were also obtained when a cold abscess communicated with the exterior by a fistula.

---

[1] Deut. med. Woch., August 31st, 1923.

but in these cases the site of the injection was apt to show a severe reaction. Most of Dr. Makai's cases of suppuration were, however, due to non-tuberculous organisms such as streptococci, staphylococci, coliform bacilli, and the like. In none of these cases did the treatment provoke progressive infection, a phlegmon, or sepsis. In about 30 per cent. there was no reaction at the site of the injection, and in another 30 per cent. a slightly painful infiltration disappeared completely and spontaneously in eight to ten days. In the remaining 40 per cent. a definitely circumscribed abscess formed at the site of injection, healing spontaneously or after aspiration. Although hundreds of such injections were given, it was necessary only in two cases to make a 3 mm. long incision. Only localised suppurative processes were, as a rule, thus treated, and among the cases there were some of suppuration in the cervical and inguinal glands, empyema, mastitis, periostitis, mastoiditis, and osteomyelitis. There were, however, two cases of severe progressive phlegmon of the neck in young children successfully treated in this manner, and one of the illustrative cases recorded in detail was that of a child, 18 months old, the right lower lobe of whose lung contained a cavity of the size of an egg. Puncture of this cavity, which was diagnosed by the X rays, yielded gaseous, greyish-yellow, thick pus containing elastic fibres, the *Bacillus fusiformis*, streptococci, and coliform bacilli. There was remittent fever reaching 39·3° C. at times, and the prognosis seemed hopeless. Five injections of 1 c.cm. of this pus were given at five-day intervals. Small abscesses with the flora of the mother abscess developed at the sites of injection. The temperature fell to 37·1° C., the exploratory puncture of the lung no longer yielded pus, the X rays showed an ill-defined shadow in the position of the former abscess cavity, and the appearance of the child was most flourishing, her weight having increased from 7·9 to 9·2 kilos in less than two months. Dr. Makai is conducting further experiments with this treatment, and he has already found that if the aspirated pus is exposed to the quartz lamp for 15 minutes before injection or is chilled for half an hour, the responses of the organism are quite different. Dr. Makai has certainly made out a case for further investigation, but this will have to be very thorough as well as confirmatory of his findings before his treatment can be accepted at his own valuation.

THE MILNE TREATMENT OF SCARLET FEVER.

IN the correspondence columns Dr. A. H. G. Burton draws attention to the great practical significance of an article on the treatment of scarlet fever which appeared in our columns on Sept. 8th, wherein Dr. G. Gushue-Taylor courageously recanted a theory of which he had been one of the principal advocates. The figures given in proof of recantation were striking, if not absolutely convincing. The fact that seems to us to rob the observations of final proof is that the figures giving the effect of return to the principle of isolation (Table A) are derived from a single year only, and from a year in which the incidence of scarlet fever was somewhat low. Figures over several years, including one in which the incidence was considerable, would carry conviction. In the same table it is noticeable that in 1920, with a total of 50 cases, there were only four return cases, a figure which is remarkably low if the eucalyptus treatment is really valueless. Nevertheless, it now seems highly probable that the facts reported by the late Dr. R. Milne are explicable on ordinary epidemiological principles. Prolonged isolation is a serious problem from educational and economic points of view, even if our experts are coming to the conclusion that mild uncomplicated cases of scarlet fever may be safely discharged at the end of four weeks; and we can only regret that Dr. Gushue-Taylor has been driven to abandon what appeared to be a hopeful alternative treatment. Nor can we feel that his remarks on the more efficient treatment of nasopharyngeal complications are very helpful, for inhalation of friar's balsam does not appear of much preventive value in other infections, and he throws no new light on the difficult choice of which tonsils to condemn and enucleate. Before resigning ourselves to the cumbersome protection of prolonged isolation, we may hope that medical officers of health, with Dr. Gushue-Taylor's admirable spirit of inquiry and progress, will make further trial with other local disinfectants such as chloramine-T.

THE REGISTRAR-GENERAL'S REPORT FOR 1921.

WE complete this week a brief summary of the concluding volume of the annual report of the Registrar-General for 1921, a report which calls for detailed study by all who wish to keep abreast of the progress of medicine in our own times. We have already singled out for special notice the section in which the writer, presumably Dr. T. H. C. Stevenson, whose name is not mentioned, illuminates the relation of tubercle to infantile mortality. This week we reproduce two charts, one of which illustrates recent remarkable changes in the age-incidence of mortality from influenza, the other the equally striking changes in that from cancer. Now that the whole "Review" (as it is now called) for 1921 has appeared it is the time to return to a consideration of the new format. The present volume is, we freely admit, handy in form and comparatively light, but further experience has not decreased our repugnance to the cramped page and the minute figures in which the tables of Parts I. and II. are printed. The change must seriously increase the difficulties of study except to the myope. It is also a hardship to the student of statistics that long months have elapsed between the publication of the tables and the text; possibly in the future a shorter interval between the three parts will be secured. The substance of the report is so well worth study that no pains would be wasted in enabling that study to be made with comfort and efficiency.

A STANDARD FOR MENTAL HOSPITALS.

ANY administrative change which would actually enforce a certain standard of treatment in mental hospitals would probably benefit the insane as a whole, provided that it carried no disadvantages in other directions. It is well known that this standard at present varies widely, and the Board of Control has no powers of enforcing changes in an institution presenting unsatisfactory features, unless a case of cruelty to a patient is proved, beyond declining to sanction transfers, a step which would be quite indifferent to the committee of the average county hospital. "Nationalisation" of mental hospitals, as suggested by Dr. A. T. W. Forrester in another column, would achieve a uniform standard of treatment, and at the same time enable the existing buildings so to be utilised as to afford separate and efficient treatment to recoverable cases. But if this "service" were made as efficient as possible, if all the varied and necessary equipment were provided, and an adequate staff paid at rates which would attract the "young, active, progressive, and best qualified members" of the medical profession (and, correspondingly, qualified recruits to the nursing profession), if, in fact, all that needs to be done were done, this service would cost not less but far more than the present cost of maintenance of the asylums. Money is the obstacle to these improvements; no one has ever suggested before that more could be done with the present expenditure of eight millions per annum; mental hospital committees, who, incidentally, work gratuitously, cannot often be accused of wasteful expenditure.

The main objection which we have to a State service is one which applies to the State management of any concern—namely, that it hampers originality and enterprise. A keen medical superintendent anxious to adopt a new form of treatment might have his scheme held up for years either on the score of expense or because some bureaucrat disagreed with or misunderstood the underlying hypothesis. At the same time some of the smaller, and in particular the private, mental hospitals would be apt to lose their traditions and individual character—assets of no small value. Outside local bodies who interest themselves in the welfare of asylum patients in a dozen different ways would feel their responsibility lessened, and much valuable work of this kind might be dropped. Dr. Forrester's forecast of uniform clothing is alarming in itself. Nationalisation should be possible without this sort of inhuman standardisation.

A CENTRAL MEDICAL INSTITUTE FOR PAISLEY.

THE medical officer of health of Paisley, Dr. G. V. T. McMichael, records in his annual report for 1922 a munificent offer. Miss Russell, of Muirfield, Paisley, intends to erect a central medical institute for the benefit of the mothers and children of the town as a memorial to her two brothers, the late Messrs. Robert and Thomas Russell. The institute, when erected, will accommodate all the various clinics conducted by the local and education authorities. Dr. McMichael pointed out in his 1921 report how severely the work of both authorities was handicapped by the hopeless inadequacy and unsuitability of the existing premises; so that no gift could have been more opportune. At the request of Miss Russell, Dr. McMichael and Dr. R. Donald, the chief school medical officer for Renfrewshire, have prepared a scheme which provides, in addition to the usual requirements of a maternity and child welfare centre, a tuberculosis dispensary and a school medical department, accommodation for clinics for minor ailments, dentistry, and eye, ear, nose, and throat affections, a remedial department for deformities, an X ray department and a disinfecting clinic for dealing with verminous children. Dr. McMichael points out the obvious advantages, from the point of view of convenience, economy, and avoidance of overlapping, in having all these clinics concentrated under one roof. A joint committee of the local and education authorities has been appointed to consider the whole question of coördination of the work. Miss Russell has approved the scheme as outlined and has appointed her architects. An ideal central site has been secured, the building will be begun without delay, and when completed and fully equipped will be handed over to the health authority, free of all cost. Paisley will be envied by other towns for being able to claim as its citizen a woman of Miss Russell's vision and generosity. Her gift is well timed in these days when public health work is hampered by lack of funds. It is also especially appropriate at a time when there is a widespread desire to secure a better coördination of the medical services employed by the various local governing bodies.

DISTRIBUTION OF ACROMEGALIC STIGMATA.

Lenz[1] recalls that while acromegaly affects several different kinds of tissue, it affects only one kind of locality in the body, for the fingers, toes, chin, nose, and ears are all distal parts. Now a very similarly distributed occurrence, not of local overgrowth but of pigment, is to be observed in one or two breeds of domestic animals, notably in a kind of rabbit called by continental fanciers "Russian," although not connected with that country. These animals are albinotic except for black ears, muzzle, paws, and tail—which parts have also a lower temperature than the rest of the body, the dividing line in the case of the ears being very sharp, for the auricle at its insertion is warm, while a millimetre or two higher up, just where the black pigment begins, it is markedly cooler. The author cites a number of experiments, illustrated by photographs, from which he deduces that the lower temperature is indeed productive of the pigmentation. If in winter time some white hair were removed from the back, the new growth was pigmented, and least so at the edges of the denuded area, where the surrounding hair might be expected to afford some protection from the cold. If summer were chosen for the experiment, the new hair showed less pigment, and particularly at the roots, where again there would be most protection from the cold; moreover, in summer the new pigmentation was not permanent, its disappearance beginning at the edges of the patch. The critical skin temperature, below which pigmentation followed, seemed to be about 25° C.; and Lenz mentions that certain ferments, such as might be concerned in bringing about pigmentation, are active only below a certain temperature. Some confirmatory circumstances are next adduced. The new-born rabbits, which, of course, in the womb or in the nests are not exposed to cold, are nowhere pigmented. The characteristic pigmentation of distal parts increases in winter and decreases in summer. Small and weakly animals showed it best. Conformably with this, breeders recommended keeping the animals in unheated hutches; moreover, the whole breed was very small and delicate, as might be expected, for clearly it was being selected for cold extremities, and so for a weak blood circulation. The peculiar "Russian" marking, to be seen in a breed of guinea-pigs and of cats (Siamese) as well as in rabbits, probably depends then upon incapacity to form pigment in presence of a temperature higher than 25° C. For this same reason—namely, that they have the weakest blood circulation and therefore the lowest temperature—may the distal parts be chosen for dysharmonic growth in human acromegaly. The essential cause is, of course, an over-functioning of the hypophysis; but its hormone may be more active at a temperature rather below that of the central parts of the body. It is also conceivable that one of the functions of this gland is to stimulate metabolism at low temperatures, for the northern European races are of more acromegalic aspect than the southern ones. This is, of course, in accordance with the view of racial characters being dependent upon endocrine influence. The suggestion is made that a desirable experiment would be for an early acromegalic subject to wear continuously a warm glove on one hand only, to see if this hand showed difference in growth from the other one.

BOARD OF CONTROL: ANNUAL REPORT.

THE ninth annual report of the Board of Control, besides providing interesting statistics, surveys as usual the events of the year (1922) in connexion with the treatment of the insane and the mentally deficient. Most of these events have already been chronicled and discussed in our columns, and it remains to congratulate the Board on their progressive attitude, their tolerance of criticism, and their manifest anxiety to use interest, when it appears even as adverse judgment, to better the conditions under which the insane are detained. It is admitted that there are many directions in which improvement is possible in the way of prevention and of cure, but it is emphasised throughout that improvements and developments must involve increased expenditure, the incurring of which the community must be prepared to sanction. If the result of agitation is to arouse in the mind of the public a permanent and not a merely fitful and evanescent interest in the welfare of those suffering from mental disorders much good may result. Some few reforms are not dependent on outlay and are being actively encouraged—for example, permission to a patient to wear his own clothing, or at least to retain the same suits, dresses, or boots when transferred to another ward.

In discussing the annual report for the year 1920, we deprecated the small amount of space devoted to an account of the research work done in mental hospitals. This year a supplement of 25 pages summarises scientific work accomplished and in progress at 12 institutions, ranging from work on the ætiology and pathology of obscure diseases to comparative studies in different methods of treatment, including the inoculation of malaria parasites in the attempt to influence general paralysis of the insane. Future research is to be even more extensive. The establishment of the Birmingham Joint Board of Research, under the directorship of Sir Frederick Mott, into the causes of mental disorder is viewed with favour by the Board, who announce their hope that corresponding research centres will be instituted in connexion with each university in England and Wales, and that with each of these centres will be grouped and affiliated every neighbouring institution in which mental cases are received. The function of these centres should be research, and should include such investigations as cannot properly be undertaken in a small clinical laboratory. This latter provision now exists in a considerable number of mental hospitals, but by no means in all of them, and it is the strong view of the Board that no mental hospital should be without one. Work should be systematically prosecuted in these laboratories, not only supplementary to post-mortem examinations, but in aid of routine clinical investigation. Further, with the institution of research centres, the Board hope to see the development of mutual coördination between them whereby interchange of information would be facilitated, results usefully compared, and needless duplication of effort avoided.

LONDON MEDICAL EXHIBITION.

ON Oct. 1st, and during the four days following, the fifth London Medical Exhibition to be held since the war will occupy the Central Hall, Westminster. We understand that the promoters have taken pains to assemble all the most modern developments in scientific appliances, preparations, and publications likely to be of interest to the medical world. The exhibition thus represents the outcome of scientific research brought into the realm of practical utility by commercial enterprise. It is a far cry to the time when the physician digged his own herb-garden and his medical books were family heirlooms; to-day commerce has advanced hand in hand with science, and we owe it in no small measure to the great medical and surgical houses that modern medicine has reached its present high level of practical achievement. The large number of doctors, not only from the metropolis, but from all parts of the world, who in past years have visited the exhibition has definitely established the value of this undertaking. The fact that the general public is rigidly excluded refutes any suggestion that this exhibition is run for trade purposes alone; experience in the past has shown that the benefits accruing to trade and profession have been mutual. It is of importance to a practitioner that he should be familiar with the products of those firms that cater for his requirements—both in his own interests and in those of his patients. The exhibition affords an opportunity to taste, see, and handle which can be had so easily and so conveniently in no other way.

Sir Archibald Garrod has been appointed to serve on the Medical Research Council to replace Prof. F. Gowland Hopkins, who retires under the provisions governing the rotation of membership.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held on Oct. 12th and 13th in the Town Hall, Carlisle, commencing on Friday at 7.30 P.M., when a discussion will take place on "Public Health Administration of Measles and Whooping Cough, from the points of view of a County Borough and a County Area," to be opened by Dr. J. Beard and Dr. F. H. Morison, Dr. T. Eustace Hill presiding. A discussion on "Some Aspects of Housing in Carlisle" will be opened by Mr. Percy Dalton, followed by Mr. A. Horsburgh Campbell, Dr. A. K. Chalmers, Dr. Kenneth Fraser, Dr. G. W. N. Joseph, Dr. Harold Kerr, Dr. E. W. Rees-Jones, Dr. J. E. Spence, Dr. J. T. Wilson, and others. On Oct. 13th visits will be paid to various works in the neighbourhood.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XXXVIII.

THE TREATMENT OF GLYCOSURIA IN PREGNANCY.

THE urine of a pregnant woman should always be examined at intervals, since albumin or sugar may be present in the urine some considerable time before any other signs or symptoms appear. Fehling's test is generally used for sugar, though it is not very delicate and may give rise to error. The error may be due to (1) bad Fehling's solution, since if the two solutions A and B are mixed, and then kept for a long time, the solution may reduce itself when it is boiled; (2) the presence of other substances, such as creatinine, uric acid, and glycuronic acid, which reduce Fehling's solution. Thus a positive test with Fehling's solution must be confirmed by other tests. The simplest of these is Benedict's, which is gradually replacing Fehling's for clinical work, as it is more reliable and gives very little more trouble; 5 c.cm., or 90 minims, of Benedict's solution and 10 drops of urine (as measured with a dropper) are boiled together. If dextrose is present in a concentration of over 0·5 per cent. there will be a precipitate in about 30 seconds after the onset of boiling, but to make certain the mixture should be boiled for two minutes. If the solution remains quite blue it means that sugar is present in a concentration of less than 0·1 per cent.; if the colour turns green it means that there is more than 0·1 per cent. present. Instead of boiling for two minutes over the flame, the test tube, after the solution has been well mixed, may be placed in boiling water for five minutes, which is perhaps an easier method for a busy practitioner.

Differential Diagnosis of the Reducing Substance.

A positive Benedict's test does not necessarily mean that dextrose is the reducing substance present in the urine, since (1) lactose, (2) lævulose, (3) a pentose, (4) homogentisic acid all give a positive test. (3) and (4) are very rare, but (1) and (2) must always be considered; the distinction between these requires some knowledge of chemistry.

Lactose may be present in the urine of a pregnant woman as soon as the breasts show signs of activity, but is usually only present (*a*) in the last weeks of a pregnancy; (*b*) after the child has been born; (*c*) if the lactation has been abruptly checked. Lactose is not fermented by yeast, and it is further distinguished by the difficulty of preparing the osazone crystals by heating with phenyl hydrazine and potassium acetate. The crystals, if formed, differ in many respects from those of glucosazone. Lactosuria is a harmless condition, which will pass away when lactation comes to an end, and demands no treatment.

Lævulose is present in the urine under certain conditions. (1) If the liver is seriously damaged, as in acute yellow atrophy of the liver, poisoning with salvarsan, or trinitro-toluene. Lævulose is often used as a test for the condition of the liver, since it may be excreted in the urine after a dose of 25 g. of lævulose. It is better to estimate the amount of sugar in the blood after the dose of lævulose, since, if it is raised at all, it is probable that the liver is considerably damaged. (2) Lævulose may be present under conditions which have no known pathological importance, and may be excreted for years without any symptoms. (3) It may be present during pregnancy; Cammidge has found that in 25 per cent. of cases, when a reducing substance is present in the urine of pregnant women, it proves to be lævulose. Lævulose reduces Fehling's and Benedict's solutions, is fermented by yeast, and gives osazone crystals which are identical with those of dextrosazone. It can therefore be distinguished from dextrose only by the fact that it rotates the plane of polarised light to the left. This test can only be made with the aid of a polarimeter. If lævulose is present in the urine during the course of a pregnancy the question of serious damage to the liver should be carefully considered, but if there is no evidence of this it is probable that the lævulosuria has no significance and the condition can be safely neglected.

Significance of Dextrose in Urine.—When it has been proved that the reducing substance in the urine is dextrose it does not follow that the patient is suffering from diabetes mellitus. Any of the following conditions may cause dextrose to appear in the urine: (1) exophthalmic goitre, (2) acromegaly, (3) renal glycosuria, (4) temporary diminution of sugar tolerance, (5) true diabetes mellitus. Exophthalmic goitre and acromegaly can easily be diagnosed and need not be further considered.

Renal Glycosuria.

With the knowledge gained from the estimation of the sugar in the blood, it has been realised that dextrose may be excreted in the urine without there being any increase in the amount of sugar in the blood, and therefore no diminution in the sugar tolerance. This condition is termed a renal glycosuria, and it is believed that the threshold of the kidney—i.e., the point at which sugar is excreted in the urine—is lower than in normal persons. This condition occurs in from 0·1 to 1 per cent. of the population, and is usually only discovered by accident, as the patients do not have any of the ordinary symptoms of diabetes mellitus. The diagnosis may be suspected from the history of the discovery of the sugar and the absence of any symptoms, but can only be made with certainty if an estimation of the blood-sugar is made at half-hour intervals after a dose of 25–50 g. of dextrose. The blood-sugar curve will resemble that of a healthy person who has a normal sugar tolerance, in that it will not rise above 0·18 or 0·19 per cent. at the end of half an hour and will have returned to normal after one, two, or three hours. Sugar, however, will be excreted in the urine in amounts of 1 to 4 g. (15–60 gr.) per hour by the patient who has a renal glycosuria. Some patients with a renal glycosuria excrete sugar when the blood-sugar is quite normal—i.e., 0·08 per cent.—while others do not begin to excrete sugar until it has risen above 0·13 per cent. or so. The diagnosis can be clinched by adding definite amounts of bread, 4, 8, 16 oz., on successive days and estimating the amount of sugar excreted. A patient with renal glycosuria will excrete very little more sugar after the 16 oz. than after the 4 oz. of bread. The total amount of sugar will vary in different cases from 5 to 30 g. (75–450 gr.). Once the diagnosis has been made the patient does not require any treatment, and may eat ordinary food. Several women who have had a renal glycosuria for many years have borne children without suffering any ill-effects, and the children do not necessarily have a renal glycosuria, although this is often the case. It has recently been shown that a renal glycosuria may be caused by pregnancy, since the threshold of the kidney for dextrose is altered during pregnancy. Sugar may be excreted in the urine, although the sugar tolerance is normal, and the blood-sugar does not rise above the normal limits. The amounts of sugar which are excreted are small, and usually only appear after a large dose of sugar—i.e., 100 g.—has been given. The correct diagnosis may be suspected from the complete absence of symptoms and the small amount of sugar which is excreted, and can be established by estimating the blood-sugar. The condition requires no treatment.

Temporary Diminution of Sugar Tolerance.

In all the conditions hitherto described there has been no reduction of sugar tolerance, but a certain number of pregnant women do develop this. The actual amount of sugar which is excreted is not large—10, 30, or 50 g. in the day. These amounts are either the same or a little larger than those excreted by patients with a renal glycosuria, so that the diagnosis cannot be made by examination of the urine. It can only be made with certainty by estimating the blood-sugar at intervals after a dose of 25 or 50 g. of dextrose. If there is a diminution of sugar tolerance the blood-sugar, half an hour after the sugar was taken, will be either already above 0·20 or quite close to this point; at the end of one hour the blood-sugar will be above 0·20, and will not have returned to normal at the end of two hours, or perhaps three or four hours. Such a curve is typical of a diminution of sugar tolerance; some information can be obtained by estimating the blood-sugar at the end of one hour only, since if the blood-sugar is above 0·20 at this point there is a diminution of sugar tolerance. The urine before the test may not contain any sugar although the blood-sugar is normal, but since many patients who are pregnant are believed to have a lowered threshold for sugar, there may be a coexisting renal glycosuria. The course which the condition runs is almost invariably favourable, since after the child is born the sugar disappears from the urine; it may reappear during the next pregnancy. The patient will need careful watching; the total output of sugar should be estimated and the carbohydrate intake reduced to a definite amount, say 4 oz. of bread. If the output of sugar is reduced to about 10 g. this reduction is probably sufficient, especially if the blood-sugar when fasting is normal, since there may be a coexisting renal glycosuria. If there is little reduction in the output it is wiser to adopt more drastic measures and starve the patient for one or two days in order to get rid of the sugar from the urine. The diet should then be gradually increased according to any of the modern methods used in the treatment of patients with diabetes mellitus. If the sugar remains absent, or is very small in amount, cautious increase in the starch food may be made: 1 oz. of bread is added every second day up to 4 oz. This procedure may be modified if insulin is used; it is probable that 5 or 10 units of insulin will enable these patients to eat moderate amounts of bread without passing any sugar, or only a trace. When the urine contains no sugar treatment should be controlled by an occasional blood-sugar estimation.

True Diabetes Mellitus.

In all the conditions so far described the patient will not complain of symptoms ascribable to diabetes mellitus, and the sugar will usually be discovered by accident. A certain number of patients do, however, develop true diabetes mellitus, and it is the fear of this complication which makes the periodical examination of urine during pregnancy important. Patients with a severe form of the disease will complain of thirst, weakness, &c., and the diagnosis will be made because the patient consults her doctor for these symptoms. But patients with a mild form of the disease may not complain of any special symptom at first, and the diagnosis may only be made in the course of a routine examination. Once it is confirmed the patient must have the full régime of diabetic treatment with periods of starvation in order to keep the urine sugar-free and the blood-sugar normal. Here insulin will alter the accepted treatment considerably, since the starvation will probably be much abbreviated, if, indeed, it proves necessary. The question whether the pregnancy should be allowed to continue, or should be terminated, must be carefully weighed. It depends to some extent on whether the patient is near term. If she is near term it is better to treat the diabetes energetically and allow the pregnancy to continue normally. If, however, the disease has started early in the pregnancy it may be wiser to terminate it. All these statements depend on the severity of the attack and the response to treatment. The influence which insulin will play is probably considerable, and no pregnancy should be terminated without very careful consideration.

First Assistant, Medical Clinic, St. Bartholomew's Hospital.

Special Articles.

STUDIES ON THE PNEUMOCOCCUS.

TWELVE months ago we reviewed in these columns[1] a report from the Ministry of Health by Drs. F. Griffith and A. Eastwood[2] on the pneumococcus. The work detailed in this report has now been followed up by a further inquiry on the same subject by these two workers[3] prefaced by an introduction by Sir George Newman. In the first section on the influence of immune serum on the biological properties of pneumococci, Dr. Griffith takes as his starting-point the old conception of a pure culture of a bacterium as consisting of a number of absolutely identical individuals. This conception he considers to be erroneous and quotes in support of his view the recent work of Arkwright and of Benians on *B. dysenteriæ* and of Mary Cowan on the streptococci. Practically all recent work, in fact, emphasises this point—viz., that bacterial variation in a pure culture is distinguishable without there being any suggestion of a true transmutation of bacterial species. In other words, in spite of variation the pneumococcus is still a pneumococcus and not a staphylococcus or other organism. By growing different serological types of pneumococci in immune serum Dr. Griffith shows that when these types are cultivated on homologous serum, growth takes place in the form of clumps and long chains or gelatinous balls which deposit at the bottom of the tube; and that when this primary culture is shaken and plated, in addition to the normal type of colony, there appears on the plate subculture a variable number of colonies of size, appearance, and consistency different from the normal colony. The normal type of colony is referred to as S and the variant as R. A second passage through serum culture yields a larger number of variants from the normal, and a third passage finds the normal S form replaced by the R variant forms. Finally, after suitable subculture a stage is reached at which a single colony culture of either type, with some exceptions, breeds true. The normal S type of colony is circular and dome-shaped, with a smooth, shiny surface and an almost watery consistency. The variant or R type is a rough type of colony, dull or finely granular, and more coherent than the normal type. At first, also, the rough variant is generally smaller than the smooth normal colony. Both are equally bile-soluble. These changes, it should be borne in mind, are all produced by growing the serological types of pneumococci in cultures of homologous serum; heterologous sera appear generally to have no power of producing the rough variant colony from the smooth normal. The latter remain stable if kept virulent by passage through animals and growth in blood broth, whereas a rough variant after retaining its characters for many generations on blood broth may revert subsequently to the smooth type. Again, the smooth normal colony culture remains pathogenic for mice, whereas the rough variant shows a high degree of attenuation. Dr. Griffith quotes a smooth type killing in 0·000,000,01 c.cm. of broth culture and a rough variant from the same original strain having no effect in a dose of 0·2 c.cm. Finally, these two types of colony are shown to have different antigenic qualities. The S type produces in young broth cultures a soluble substance which the R colony does not, the former agglutinates with specific serum with a firm gelatinous precipitate, the latter produces loose clumps which are readily shaken up, whilst other immunological distinctions (e.g., with absorption) are also noted.

Dr. Griffith points out that here we have a definite morphological criterion for distinguishing between virulent and attenuated strains, and that immune sera should always be prepared entirely from S type cultures. The alteration from the S to the R type he considers to be a degenerative tendency present in many bacterial strains, and is therefore consonant with the work of other observers quoted at the beginning of our review. The S and R types possess related antigens but R lacks an antigen contained in S; witness the results obtained in absorption experiments. The author believes that an explanation of these phenomena can be found in the intimate association of the pneumococcus capsule with the existence of virulence. Briefly it is the outer portion of the pneumococcus which is modified in the change from smooth to rough type of colony—hence the latter loses the typical smooth, shiny surface and watery consistency and becomes dull and granular, whilst the individual cocci tend to adhere. This modification, it is suggested, is due to a substance soluble in salt solution which is not secreted in the attenuated R type of colony and which is intimately concerned with the virulence and capsule formation of the S type.

In the second part of this report Dr. Arthur Eastwood discusses the questions raised by his colleague's work of bacterial variation and transmissible autolysis and the relation of bacterial enzymes to bacterial structures. He points out that bacterial variation is no mere haphazard quality, but that it tends always to some one definite direction, and he shows how in the process of reproduction aberrant or variant forms may conceivably, on theoretical grounds, occur. Thus the transmissible lytic substance of the Twort-d'Hérelle phenomenon is not merely an agent for destroying bacteria but a method of producing bacterial variants. We are thus faced with the biological problems of variation and reversion to type, probably intimately bound up with questions of virulence. Dr. Eastwood sums up a most interesting and thoughtful memorandum by formulating a general statement that the constituents of living protoplasm have two functions: (1) a catalytic action which prepares food material by means of appropriate enzymes, and (2) a synthetic action by which new protoplasm is built up. He suggests that the balance between these two functions may be very finely adjusted and any disturbance of it may lead to the production of bacterial variants.

The Medical Research Council Report.

This report has now been succeeded by one from the Medical Research Council[4] which approaches the pneumococcus from the standpoint of the clinical pathologist, and the two together make a valuable study of this organism, pointing the way to the solution of many bacteriological and clinical problems which have hitherto made this subject the battleground of many inconclusive struggles. The first part of the report of Dr. E. E. Glynn and Miss Lettice Digby is concerned with laboratory technique in which the various modern methods of investigation are detailed—and their name is legion. No good purpose would be served by reviewing these in detail, but we believe the authors have maintained throughout a well-balanced perspective. We would, for our part, heartily endorse their opinion that bacteriologists, as a rule, make far too little use of low-power binocular lenses for plating and culture work generally. Bile solubility also is better tested with deoxycholate than with whole ox bile and can be controlled more readily with the microscope. We also confess to a deep sigh of relief to find that sugar fermentation tests are relegated to a relatively subordinate position. En passant it is becoming more and more urgently necessary for bacteriologists to agree on a more or less standardised method for estimating hæmolysis of blood media. But these are merely technical points, and for most readers the main interest of the report will lie in fresh light it throws on the various bacteriological aspects of pneumonia; 140 cases of pneumonia and 50 of acute empyema were investigated by the authors, as well as saliva from normal controls and a group of miscellaneous pneumococcal and streptococcal infections. The authors found that in the case of sputum or saliva the mouse inoculation test yielded the most certain results for the finding of pneumococci, whilst streptococci, on the other hand, usually came out best on direct plate cultures. Lung-juice cultures obtained by means of exploratory puncture with a 10 c.cm. record syringe and a medium needle are advocated as a safe and valuable aid to diagnosis. In adults 45·1 per cent. and in children 61·5 per cent. examined in this way yielded positive results and afforded a reliable guide as to clinical prognosis, the mortality amongst positive cases being 50 per cent., as against 9·1 per cent. in the negative cases. The blood culture findings were equally striking, 45 per cent. showing positive results with a mortality of 71·4 per cent. in the positives and 8·3 per cent. in the negatives. The authors also isolated 23 strains of intermediate pneumo-streptococcal strains. Most of these were eventually assigned to one or other group but five strains remained definitely unclassifiable, their colonies being intermediate in character, their morphology generally diplococcal in serum broth and other crucial tests equivocal. These so-called intermediate pneumo-streptococcal strains are a source of much confusion in all bacteriological investigations made via the mouth, and chronically enlarged tonsils in our experience are particularly liable to harbour them. It is interesting to note that in the report under consideration a larger number of these intermediate types were ultimately classified as pneumococci then as streptococci. Whether or not we are encountering here the question of bacterial variation it is impossible at present to say, but the question is worthy of detailed investigation.

[4] Bacteriological and Clinical Observations on Pneumonia and Empyemata, with special reference to the Pneumococcus and to Serum Treatment. By Ernest E. Glynn, F.R.C.P., and Lettice Digby. Published for Medical Research Council by H.M. Stationery Office. 1923. 5*s.*

Space does not admit of a discussion of the various points raised with reference to the typing of the pneumococci, the classification of streptococci, and the identification of the numerous other organisms isolated from these pneumonia, empyema, and miscellaneous infections, but the question of clinical and bacteriological correlation cannot be passed over. In the empyemata of young children the Type I. pneumococcus cases were more often secondary to pneumonia than the Group IV. pneumococcus and the streptococcus cases. Also on the average the Type I. pneumococcus cases had a higher temperature and in the recoveries a shorter illness than the others. Amongst the pneumococcal pneumonias onset with rigor and termination by crisis was commoner with the Type I. cases than with Group IV. cases, whilst the temperature of Type I. cases was of shorter duration, more often continuous, and the sputum more often rusty than in Group IV. cases. It would seem, therefore, that Type I. pneumococcus produced the more typical clinical type of case, and this may not be without bearing on the larger bacteriological issue when we consider the fact that Group IV. pneumococcus is such a heterogeneous collection. It was also further noted that cases beginning with rigor had a heavier plate incidence of pneumococci than those whose onset was gradual. We cannot but regard this correlation of clinical and bacteriological findings as extremely valuable, as it is by means such as these that diagnosis becomes an accurate business. Indeed, reviewing these and other acute infective diseases of known bacterial origin we should say that the most notable advances made of recent years have been in the direction of rendering diagnosis more accurate, and in the long run more efficient treatment must surely follow. The authors of this report conclude by pointing out that the mortality from pneumonia, excluding influenza, is slowly increasing in England and Wales and is now greater than that from phthisis. To quote their concluding sentence: "A systematic investigation, by standardised methods, at a few centres in Great Britain, of the flora of normal mouths and of bronchitic and pneumonic sputa would furnish valuable information regarding factors governing the incidence of, and mortality from, pneumonia and influenza."

VITAL STATISTICS FOR 1921.

THE REGISTRAR-GENERAL'S REVIEW.

(*Continued from p. 582.*)

Causes of Death.—The first causes of death considered in the Review are the acute infectious diseases. Among these *enteric fever* is rapidly becoming a disappearing disease. In 1921 it was responsible for only 613 deaths, as compared, for instance, with nearly nine times this number in 1890 in a much smaller population. The death-rate in 1921 was only 16 and in 1920 was only 14 per million of population, the lowest figures hitherto attained. It was much higher in the north of England than elsewhere, and, strangely enough, was slightly higher in the aggregate rural districts than in London.

Fatality of Certain Infectious Diseases.—On page 40 is an interesting table showing the case-mortality of some of the chief infectious diseases. The rates are given with reserve, owing to possible defects of notification, and because in the case of small-pox the number of cases is too small to have significant rates based on them. Between 1911 and 1921 the case mortality of enteric fever varied between 15·8 and 20·6 per cent., of scarlet fever between 0·95 and 2·0 per cent., of diphtheria between 7·2 and 10·9 per cent., while that of small-pox (subject to the above-mentioned warning) varied from 1·6 to 42·9 per cent. The corresponding percentages for poliomyelitis and meningococcal meningitis indicate defective notification of cases.

Measles.—The figures for measles are regarded in the Review as indicating the possibility that "a new era in this disease may have opened." Stated in terms of the population at ages under 15 years, the death-rate from measles in 1921 was 206 per million, and the rate in 1920 was less than half the rate for any year prior to 1916. (To pursue this comparison another volume than the one under review needs to be consulted; the result only is stated in this volume.) For two years in alternation the death-rate from this disease has been unprecedentedly low, with a low rate between these two years. It may be hoped that increased attention to child life and the growing efforts to visit and nurse cases of this disease are beginning to show their effect.

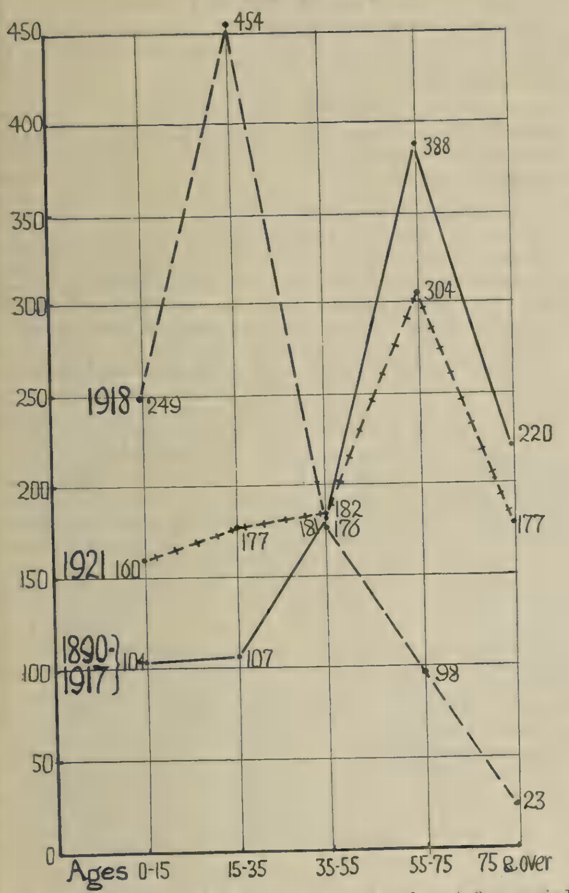
Scarlet fever has become a relatively innocent disease, so far as concerns death. In London it was prevalent three to four times as much as in rural districts, with a rather lower fatality.

Diphtheria shows much activity. From 1891–95 to 1911–15 it had declined, but this process has now ceased.

Influenza.—This disease at the outset of the great epidemic of 1918 underwent a sudden and remarkable change in the age incidence of its death-rate which has not been satisfactorily explained, and which, owing to its international distribution, can only be partially elucidated by the events of the great war. Although this cannot be discussed here, it is important to note, as shown in the following diagram, that the age distribution of influenzal mortality is steadily reverting towards the earlier type. In Fig. 1 the proportions of deaths at five periods of life are given for 1890–1917, for 1918, and for 1921, for females only, to permit of comparisons during the war, and standardised for age distribution. The extraordinary change in age incidence of mortality in 1918 is seen, and the reversion towards the earlier type in 1921.

Decline of Mortality from Tuberculosis.—This section contains the most complete review of the historical course of the death-rate from total tuberculosis, and from pulmonary and from non-pulmonary tuberculosis in this country which has hitherto been published. The death-rates from each of these forms of tuberculosis are given and the death-rates at all ages in the aggregate are standardised; in this way the differences due to varying proportions of

FIG. 1.



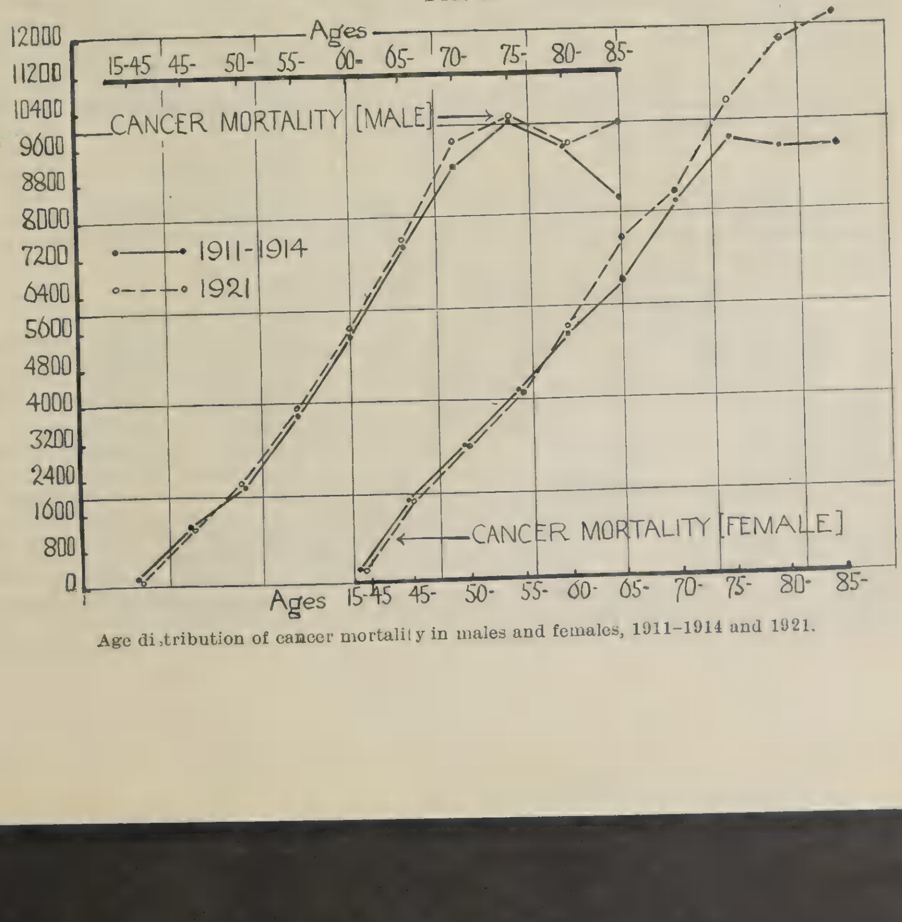
Proportions of deaths from influenza of females at five periods of life during 1890–1917, 1918, and 1921.

persons living at various ages being eliminated. Death-rates are given for each year from 1851 onwards, and summarised death-rates for decennial and for quinquennial periods. Attention was drawn in a recent issue[1] to the difficulty in interpreting statistics of various forms of non-pulmonary tuberculosis in infancy. As a large part of non-pulmonary tuberculosis occurs in infancy, the figures for pulmonary tuberculosis must be regarded as on a higher plane of certitude than those for total tuberculosis. Even for pulmonary tuberculosis in certain years there may be divergences from the usual course of events. This was to an exceptional extent the case during the great war, and following that in the great influenza epidemic of 1918–19, when the falling death-rate from pulmonary tuberculosis was replaced by an increasing death-rate which reached its maximum in 1918. The special causes for this increase and its distribution in certain special age-periods are discussed in other official reports by Dr. Stevenson. Here we are concerned solely with the general course of events, which has been resumed now that the disturbances caused by war and by influenza have disappeared.

Curves for total tuberculosis, given in the Review, show a surprisingly constant decline during the whole period 1866–1914, and this position has been resumed in 1920 and 1921. This constancy, as is pointed out in the Review, is not in the rate of fall, which has been increasing, but in the actual amount of fall. To bring out this point the course of events is charted not only for actual rates, but also on a logarithmic scale, thus enabling changes in death-rates and in rates of fall to be readily compared. With pulmonary tuberculosis the trend of events for males has been similar to that for total tuberculosis, the rate of fall having been consistently on the increase, while for pulmonary tuberculosis in females a particularly rapid fall was experienced from 1890 to 1896, while since then there has been some falling off in the rate of decline.

The decline in the death-rate from tuberculosis may be regarded as the resultant of forces, some of which tend to increase and others to reduce it, and the fact that the rate of decline has not increased so rapidly as may have been anticipated in view of the active anti-tuberculosis measures of recent years, gives ground when duly considered for encouragement. Even a stationary death-rate from tuberculosis, having regard to the increasing complexity of modern life, to the great increase of human communications, to the replacement of country by town life, to the increase of indoor and sedentary as contrasted with outdoor occupations, might reasonably be regarded as evidence that the improved hygienic habits of the people, the diminished amount of indiscriminate spitting, the improved nutrition of the population, the more successful treatment of the disease, and the hospitalisation of a large proportion of advanced and acute cases, in conjunction, are telling on the total mass of the disease. But instead of a stationary death-rate, we find that the death-rate from tuberculosis continues to decline, and so far at an increasing rate. There is every reason therefore to pursue active measures on all known lines of prevention of treatment, while welcoming any advances in therapeutics or in preventive measures

FIG. 2.



Age distribution of cancer mortality in males and females, 1911–1914 and 1921.

---

[1] THE LANCET, Sept. 15th, p. 575.

that experience or scientific research may render available.

Cancer.—This disease now bulks more heavily in the death returns than tuberculosis, 46,022 deaths—20,649 of males and 25,373 of females having been returned—as cancer, as compared with 42,678 from tuberculosis—22,899 of males and 19,779 of females. In Fig. 2 is shown the course of the age distribution of cancer mortality in males and females, and it will be seen that after 45 for males and 60 for females the rates for every age-group are higher in 1921 than in 1911–14, while below these ages they are lower.

The partial shifting of the stress of cancer mortality towards the latter end of life, which remains when all fallacy caused by the greater number of survivors at these ages has been eliminated, is not peculiar to English experience. In recent returns for New Zealand, for instance, attention, we are informed, has been drawn to this change.

Among other interesting details as to the distribution of cancer, special attention should be drawn to the remarkable differences in the incidence of fatal cancer of the genital organs according to marital condition. Standardised death-rates being unavailable for this comparison, the relative excess of deaths from cancer of each genital organ over that for deaths from all causes is given, according to age, and in married and widowed women as compared with single women. There is excessive mortality among the married from uterine cancer, occurring chiefly in the reproductive period, and reaching its maximum of 210 per cent. at ages 35–40. Along with this goes the fact that the uterus is the only important seat of primary cancer mortality in which cancer does not appear to be increasing, a result which might be expected, in view of the lowered birth-rate, if injuries in childbearing have any relation to excess of cancer. On the other hand, cancer of the ovaries and Fallopian tubes shows as great a predilection for single women as uterine cancer for the married, but this excess only slowly emerges during the childbearing period. So also with mammary cancer, the excess from this form of cancer in the unmarried increases rapidly after the childbearing period. The complete significance of these important facts will be better seen when it becomes practicable in a later report to give death-rates for each age-period and for each variety of cancer. That they will be found to have much bearing on preventive medicine cannot be doubted.

The entire report calls for detailed study by all who are interested in medicine, either in its curative or its preventive side.

THE MEETING OF THE BRITISH ASSOCIATION.

SECTION OF PHYSIOLOGY.

THE papers read at this section may be divided, for purposes of description, into three classes—medical, pure physiological, and theoretical. Prominence is given to the contents of the papers in accordance with this order, though a strict demarcation of subject-matter is not actually possible.

The presidential address by Prof. G. H. F. **NUTTALL**, F.R.S., dealt with Symbiosis in Animals and Plants, and naturally attracted a large audience of botanists. The address was very broad as well as deep, and does not lend itself to abstraction, as it was developed in considerable detail.

In a paper on the Relation between Diet and Cancer, Dr. S. **MONCKTON COPEMAN**, F.R.S., developed a hypothesis which rests on the idea that since cancer tissue is of juvenile type, and since fat-soluble A-vitamin is more essential for the nutriment of young than of adult tissues, that reduction of the vitamin-A content of the diet might exert some differential effect on the growing tumour.

Dealing with the subject of Dental Caries at Porto Santo, Dr. **MICHAEL C. GRABHAM** stated that the natives of this island are almost immune from caries, and suggests that this is due to some constituent of the highly mineralised water. The teeth of the district are characterised by the appearance of a thin yellow line across the upper incisors, and in later life this stain spreads and stains the teeth generally. It is, he said, not seen in Madeira.

Prof. J. M. **BEATTIE** dealt with the

Action of Finely-Divided Particles of Slate on Toxins.

The work started from the observation that workers in slate quarries did not suffer from rheumatism, although they often had bad teeth. It was an established fact that certain substances, such as asbestos, could destroy toxins *in vitro*, and extension of these experiments showed that the same property was possessed by finely-powdered slate, 2 g. of which could destroy 10 lethal doses of diphtheria toxin, if the slate was sufficiently finely divided. The action is effected in a few minutes, and the toxin is absent from the slate itself as well as from the supernatant fluid. Although other fine siliceous powders such as kieselguhr, clay or silica, can do the same thing, the presence of silica is not essential to the reaction, which can also be effected by a variety of other finely particulate substances such as charcoal, bismuth salts, &c. The use of these two last-named substances in dyspepsia is of interest, and it was suggested that by adsorbing the toxins, the bacteria were rendered inert and were more easily destroyed. Hæmagglutinin, agglutinin, and complement were also adsorbed by slate, and live bacteria mixed with slate dust were rendered non-lethal, in spite of the fact that live bacteria could still be recovered from the site of injection of the mixture. The antigenic power of serum was unaltered by slate, a fact which might perhaps find some further application, for it enables us to remove the toxic substances without destroying the antigenic properties.

Prof. H. E. **ROAF** described a method for

Measurement of Colour-Blindness in Terms of Wave-lengths,

which is certainly recommended by its simplicity. The subject is given a standard diagram in colours, which he is told to fill in on a blank; the diagram is then examined, together with the standard, by viewing them though coloured screens which cut off certain wave-lengths. When a match is found the deficiency of the patient's vision, as compared with the observer's, is given by the wave-lengths of light absorbed by the viewing screen which gives the match. Colour-blind subjects fell into three groups, of which the first was deficient at the red end, the second up to the sodium line of the spectrum, and the third up to the violet end—i.e., was totally colour-blind. Dr. F. W. **EDRIDGE-GREEN**, in a paper on the effect of the blood of the retina on colour matchings, pointed out that this must be allowed for in comparing colour matchings of foveal with marginal parts of the retina.

A most ingenious recording kata-thermometer, devised for Prof. L. **HILL** by Dr. E. **SCHUSTER**, was demonstrated by Mr. T. C. **ANGUS**. This instrument allows of a graphic record being made to show the rate of cooling in the air, and should prove very useful for the investigation of ventilation problems by the use of the kata-thermometer.

Prof. J. J. R. **MACLEOD**, of Toronto, gave a popular lecture on Insulin and its Value in Medicine,[1] which was attended by a large audience in the Picton Hall. Most of the subject-matter will be familiar to those interested in the subject, but it is worth mentioning that Prof. Macleod laid stress on two points of some current interest in connexion with recent claims. One is that there is at present no evidence that insulin can produce any of its effects when given by the mouth.

---

[1] THE LANCET, Sept. 22nd, p. 591.

The other point is that since we do not know the exact chemical nature of insulin, except that it is a very complicated substance, any hopes of synthesising the principle are doomed to disappointment, at least for a long while to come.

Some Pure Physiology.

Papers of pure physiological interest comprised one by Prof. H. Zwaardemaker, of Utrecht, on Bioradioactivity, or the importance of potassium and other radioactive elements in the life of the cell, and one by Prof. R. Magnus, also of Utrecht, on the effect of carbon-dioxide on the lungs; he showed that carbon-dioxide in physiological concentrations, and in presence of extremely minute amounts of adrenalin, causes dilatation of the bronchioles and pulmonary vessels, thus facilitating the inlet of air and the circulation of blood through the lungs. Prof. Ramsden and collaborators read papers, and showed very pretty demonstrations dealing with various phenomena in physical chemistry. A somewhat similar subject was dealt with in a joint discussion with the Chemistry Section on the Physical Chemistry of Membranes in Relation to Physiological Science. The discussion was opened by Prof. Roaf, who gave an account of some important phenomena in physiology in which membranes played a part, or might possibly have to be considered as playing a part.

Prof. F. G. Donnan then gave an account of the physico-chemical aspect of membranes, and expressed the opinion that much of this part of physical chemistry had only a remote bearing on physiology, because in the past it had dealt with states of thermo-dynamic equilibrium. He said that the activities, and indeed the very existence, of a living organism depend on its continuous utilisation of an environment that is not in thermo-dynamic equilibrium. A living organism is a consumer and transformer of external free energy, and environmental equilibrium means non-activity and eventual death. It was, indeed, a pleasure to hear such a distinguished physical chemist express views so broad and so sympathetic to biology, and gave one to hope that the omniscience of the physical chemist is a thing of the past generation.

Other papers of pure physiological interest were contributed by Dr. S. C. Brooks on Electrolytic Conductance of Micro-organisms; Dr. W. W. Waller on Red Blood Corpuscles under the Microscope; Prof. C. Lovatt Evans on the Contraction of Plain Muscle; Prof. Roaf on the Mechanism of the Cochlea, and on the Oxygen Content of Methæmoglobin, which he, with Buckmaster, believes to be only half that of oxyhæmoglobin; Mr. J. C. Waller on Photo-electric Currents in Leaves; Prof. J. S. Macdonald, with Dr. F. A. Duffield, papers and a demonstration on the Energy Cost of Cycling; Prof. J. S. Macdonald, with Miss Margaret Macdonald, Mr. George Macdonald, and Dr. T. W. Wadsworth, on the Physiology of Walking. There was also a paper by Mr. Watson-Jones on the Metabolism of the Frog at Different Temperatures.

The meeting was well attended, the local arrangements were excellent, and on the whole it was the best meeting of the section held since the war.

SECTION OF ANTHROPOLOGY.

In this section the presidential address by Prof. P. L. Newberry showed that in the delta of the Nile, long before Menes, the first king of Upper and Lower Egypt, there had been a contact of races from Lybia on the one hand and Asia Minor on the other, with the autochthonous predynastic peoples. From this contact arose the Egyptian civilisation. Research is proceeding which may elucidate the relative importance of the various elements. In a further paper Prof. Newberry drew attention to the importance of studying the origin of the domesticated animals and plants found in Egypt. There were evidences that the cereals came from Syria, but many weeds seemed to come from farther East. The goat was probably responsible for the disappearance of the olive by eating the shoots of young plants, while the camel, by close cropping, drove away the antelopes, and so the carnivora who preyed on them. In the discussion Prof. G. Elliot Smith suggested that barley really came from Somaliland, and indicated an infiltration of civilisation from the south rather than the north. Further research is proposed, and any evidence of the nature of weeds associated with cereal crops might be of great assistance.

Prof. Sollas, of Oxford, read a paper on the evidences of Miocene Man, derived from certain flints from the province of Cantal in France, found in deposits of Pontic age on the rocks of the Miocene and Pliocene periods. In certain cases, as for example, in the Hastings beds at the base of the Eocene, erosion of underlying formations may lead to such pressure on flint pebbles that they flake in a manner similar to that produced by human agencies, and these flakes may deceive the very elect, but in this instance the formation was such that, so far as Prof. Sollas can see, all non-human agencies can be excluded. If true, this greatly extends the history of an intelligent precursor of homo sapiens on the earth, and goes far to confirm the views of Sir Arthur Keith.

Sir Arthur Evans gave an account of his recent work at Knossos, showing the origin of a road from the palace gates which passes to the south of the island, facing Africa, so that navigators could reach Africa without passing the dangerous capes at the ends of the island. This may explain the mutual relations of Minoan and Egyptian cultures, if not even some intermingling of races.

Dr. Kruyt described a stone-using people of Central Celebes, who erected menhirs to their dead and were acquainted with bronze. They preserved the bones of the dead in pots they named "vessels," indicating a former intention and perhaps practice of sending the dead home for burial. This has a bearing on the theories of race or culture dispersal from a point on the European border.

Mr. W. E. Armstrong pointed out that on Mossel Island there was a ceremonial consumption of one or more persons on the death of a chief. Sometimes the victim offers himself voluntarily; at other times force must be used or strangers used for the purpose. There is also a peculiar form of pseudo-marriage, in which a woman, owned by several men unable individually to support a wife, is let out on hire on festive occasions for the benefit of the partners.

Mr. W. Bonser, in a study of the magic practices of the Finns, showed these people had Eastern and not Western affinities. The shaman was only able to perform after working himself up into an hysterical stage, and the office was hereditary in a few families.

Prof. Fleure reviewed the pre-history of Wales, showing the survival of ancient types, and Dr. Wheeler indicated from a study of hill forts how incomplete had been the Romanisation of the Principality.

INDIGENOUS SYSTEMS OF MEDICINE IN INDIA.

REPORT OF THE MADRAS COMMITTEE.

Our Madras correspondent has given the conclusions arrived at by a committee appointed by the Madras Government to consider the recognition of Ayurvedic medicine in the Presidency.[1] The full report, signed by all the members of the committee, is now available; it is moderately brief, but is wholly based on a very cleverly written memorandum on "The Science and the Art of Indian Medicine," prepared by Dr. Srinivasa Murti, the secretary. This memorandum is published along with the main report, and occupies 96 printed foolscap pages, as compared with the 44 pages of the report, and it will not promote the encouragement of the indigenous systems.

---

[1] The Lancet, 1923, i., 1231.

Dr. Murti's Conclusions.

Dr. Murti claims to have studied the Indian systems of medicine from the two necessary standpoints, viz.: (1) as a science, and (2) as an art. To begin with his conclusions, they are: (1) The Indian systems are undoubtedly scientific, and their general principles and theories are quite rational and scientific; (2) as an art and as practised at present Indian systems are not self-sufficient, because while they are self-sufficient and efficient in medicine, in surgery they are not.

Six long chapters, some of which contain much irrelevant matter, follow, viz.: (1) Scientific methodology; (2) subjects of preliminary scientific study—the panchabhuta theory; (3) physiology and anatomy—the thri-dhatu theory; (4) ætiology and pathology—the thri-dosha theory; (5) diagnosis and treatment—the rasa-guna-veerya-vipaka-prabhava pharmacology; and (6) Indian systems judged from the standpoint of art.

Science and Mysticism.

It is clear that Dr. Murti depends far too much on the opinions of European "authorities," who would be more correctly called "cranks" in European scientific circles. The line of thought appears in this sentence: "Every system of Hindu thought is at once philosophy, science, and religion, all in one, and one in all." It is always urged against criticism of Ayurvedism that the critic must first learn Sanskrit, then study Ayurveda for several years, and become imbued with the spirit of Hindu philosophy before he can deliver any judgments. If the upholders of Western medicine agreed to this, Ayurvedism would stand practically unassailable. If the professors of Ayurveda intend to incorporate mystic rites with religious ceremonies and Vedic texts, and to maintain that the outcome is a system of medicine, they must remain a cult apart. Dr. Murti's statement that "it is quite as scientific for Ayurvedists to assume the truths of Samkhya and the like as it is for the student of Western medicine to assume the truth of modern physics and chemistry," traverses too much accepted knowledge to make communion possible.

In the chapter on "Preliminary Scientific Study in Ayurveda" an attempt is made to prove that European and Hindu theories of matter are in very close agreement, and that the modern conception of the atom finds its parallel in Hindu scientific thought from the commencement. It is also stated that the original propounders of such theories as that of the evolution of the atoms were persons endowed with immense ranges of vision, because the old Hindu gurus or teachers, "by improving their own internal organs of sense," could extend their range of perception to any desired degree, even to perception of an atom. The microscope and other scientific instruments cannot be thus set aside.

Ayurvedic "Humoral" Theory.

In the chapter on physiology and anatomy further attempts are made to show that modern physiology is gradually coming round to the ancient "humoral" Ayurvedic theory, and that "hormones" and "enzymes" are merely new words for "special chemical complexes," which were thoroughly understood and worked out by the ancient physicians of the indigenous systems. But the mysterious "humours," called Vata, Pittha, and Kapha, must pass through modern physiological laboratories before it can be claimed that these "dhatu-triads" correspond exactly to the catalysts, enzymes, hormones, and other activating agencies of modern Western physiology. Dr. Murti, enthusiastic as he is, seems to hesitate before making the claim, and merely pleads for an understanding study of the ancient Ayurvedic physiology. In anatomy it is admitted the loss has been very heavy, all original works having been lost, and later writers did great harm to Ayurvedic literature by burdening their writings with a "fanciful anatomy" of their own invention.

The chapter on ætiology and pathology is written in the same frame of mind. It is stated that Ayurvedists hold that the only ways in which the body could be invaded are through the mind and senses; hence the subjective Ayurvedic classification of causes of disease is complete and comprehensive, whilst that of modern medicine, which states that invasion of the body is carried out by external agencies of disease, is only objective and therefore imperfect. As regards the bacterial causes of disease, the memorandum goes rampant, quoting, for instance, Sir James Goodhart's Harveian oration for 1912, "even bacteria are probably results and not causes," and pleading that the Ayurvedic thri-dhatu (humoral) theory is what modern research is being driven to recognise, and that there seems to be an essential similarity, if not identity, between the two modes of thought.

Indian Methods of Diagnosis.

Ayurvedic diagnosis of disease is carried out by means of the five senses and by interrogation, whilst examination of pulse and urine have received considerable attention. Some Ayurvedic practitioners even claim that sex, pregnancy, &c., can be diagnosed by examination of the urine, and this claim is supported by the assertion that "if it is possible to diagnose pregnancy by the presence in the blood of an enzyme capable of digesting placental proteins, why should it be impossible to diagnose the same by an examination of the urine?" The method of examination to be adopted is not mentioned, but in any case the above quotation is an illuminating sidelight on the attitude adopted by Dr. Murti, himself trained and qualified in Western medicine.

In the section on treatment it is stated that Western-trained medical men often failed because they did not possess the key to the diagnosis of the *patient*, though they were quite correct in their diagnosis of *disease*. Western medicine apparently has no means of recognising a patient's *prakriti*, or inherited constitution, but acts more or less blindly, and learns from the bitter experience of its patients. Why this prejudiced assertion is made without any proof is not stated, but it again illustrates the writer's mentality. Dr. Murti adds that the category of thadarthakari remedies (a series which produce the same condition as the cause of the disease itself) is wide enough to include all forms of vaccine therapy known to Western medicine. Hence, it is presumed, the promiscuous and dangerous use made in India to-day of all kinds of serums and vaccines! Dr. Murti admits that Ayurvedic diagnostic methods are mostly clinical in contra-distinction to the laboratory methods of Western medicine, but ends by pleading for "a harmonious and judicious combination" of the two. It is impossible to follow him when he maintains that it would be dangerous and even disastrous for a Western medical man to use Ayurvedic remedial measures without an understanding of the principles of Ayurvedic pathology. There can surely be only one scientific system of pathology. Again, the statement is made that "various kinds of vaccines are made from fæces, urine, expectoration, and foul matter from pathological secretions and excretions of various kinds." This statement is used to ridicule the British Pharmacopœia, but Ayurvedists themselves give crushed gall-stones as a medicine and have been known also to prescribe "fresh urea" in the form of cow urine.

Self-sufficiency of Ayurveda.

Finally, under the heading "Is Ayurveda self-sufficient at present?" it is admitted that it is necessary to utilise the services of the Western system in the branches of medicine, surgery, midwifery, ophthalmology, medical jurisprudence, bacteriology, and anatomy; and the stethoscope, the microtome, X rays, polygraphy, the electroradiograph, the cystoscope, &c., are all to be made use of, as is electrical or radium therapy, quinine, emetine, and antimony. "It cannot be that water is H_2O in the west and something else in the east." This fatal admission, made by Dr. Murti, refutes all the laborious arguments he has made, for if water is H_2O in both east and west, can scientific pathology and physio-ogy differ in the two hemispheres ? At present the Ayurvedists admit they have neither teachers nor text-books with which one would expect them to place their system of medicine on a scientific footing. This note cannot be concluded in any better way than by quoting another sentence from the memorandum : "In so far as the one common ideal of all systems of medicine is the preservation of health and the prevention or cure of ill-health, there can really be but one system of medicine" ; but that this is not a widely-accepted opinion among Ayurvedists appears from a recent letter to the press from an Ayurvedic physician, who states that "absolute fusion can never be achieved, for Ayurveda will never consent to lose its characteristic of thinking in terms of its own peculiar religious philosophy of Satwa Rajas and Tamas."

No Hope of Fusion.

There can be no hope of fusion with modern scientific advance so long as this opinion is held. The same writer tries to answer the argument that the Government cannot be asked to place the Ayurvedic systems on a definite footing until they have put themselves in a position which can be recognised as a body and a teaching profession, by pleading that the present obnoxious rite of vaccination could never have survived against the attacks of very able exponents of Western medicine unless it had been bolstered up by Government. This is the level of argument used, and the ignorance displayed, by one of the ablest exponents of the Ayurvedic systems. No Government recognition should be given until the Ayurvedists are prepared to come out into the open, to produce a syllabus for teaching, and to state their methods for the treatment of diseases, so that the scientific world may have some definite proposition to work upon.

INSULIN MEDICATION:

A COMPENDIUM OF EXPERIENCES.

RECENT issues of the *Journal of Metabolic Research* contain numerous papers by different workers in Canada and U.S.A. who have all been working at the treatment of diabetes mellitus with insulin. Vol. II., Nos. 5 and 6, though dated November and December, 1922, contain papers which were received for publication as late as May, 1923 ; this makes for some confusion. All the workers agree as to the great value of insulin, but they differ widely as to the best method of using it. They may be divided into two schools just as the English workers are—those who aim at keeping the blood-sugar normal, and those who pay most attention to the clinical condition and do not mind if the blood-sugar is raised. F. G. Banting, W. R. Campbell and A. A. Fletcher, and F. M. Allen and J. W. Sherrill agree that the fasting value of the blood-sugar should be kept as near normal as possible. E. P. Joslin, R. M. Wilder, J. R. Williams, R. Fitz, H. Geyelin, R. T. Woodyat, and their co-workers all seem to agree that the clinical condition comes first and that the blood-sugar is a secondary matter.

The manner in which the diet has been arranged also differs considerably. Most workers have been using a diet arranged according to Woodyat and Shaffer's principles of the aketogenic ratio and to the basal metabolism. Allen has been using the latest modification of his method which differs considerably from the original method which is still in use in this country. The end-stages of his two plans do not differ very much from each other. The actual amount of carbohydrate which has been given by the different workers has varied, considerably. The dosage likewise has been varied, and it has been necessary in most cases to give two or three doses in the day before the meals at which carbohydrates have been eaten. The following special points demand attention.

Recovery of Tolerance.

Banting, Campbell, and Fletcher point out that recovery of tolerance occurs in some cases, which render the work of estimating how many grammes of carbohydrate are looked after by 1 unit of insulin quite misleading. Especially good results are reported with three children ; in one case the blood-sugar was kept at the normal level, but in the third there was no increase in sugar tolerance, although the child had nearly doubled her weight. They lay stress on the fact that while the diet may be increased to any desired amount provided sufficient insulin is given and the patient kept aglycosuric the proper balance of protein-fat and carbohydrate cannot be neglected ; also, that rest for a weakened organ is a fundamental principle of therapeutics, and that efficient rest may be achieved by the use of insulin and thus give a chance of recovery of sugar tolerance. Patients with septic conditions can take big doses of insulin without showing the signs of hypoglycæmia.

Diabetic Coma.

The treatment of diabetic coma is specially dealt with by Campbell, who comments on the whole question of ketosis. He believes that large quantities of sugar should be given to patients in coma together with large doses of insulin in order to ensure that hypoglycæmia does not occur. The results of such treatment in his hands have been very satisfactory. Fletcher and Campbell have a separate paper on hypoglycæmia and its complications. They found that the level of blood-sugar at which symptoms occurred varied in different persons. Some patients had symptoms when the blood-sugar was only 0·08 per cent., whereas others could tolerate a blood-sugar of 0·06 per cent. without any inconvenience. A good account of the symptoms of hypoglycæmia is given. The first symptom is often nervousness followed by excessive hunger or inertia. This is followed by sweating and pallor, and in children the pulse rate is increased. At a later stage tremor is present and there is a loss of the fine movements of the hands. Aphasia, both motor and sensory, may occur together with great excitement. Syncope may occur and the patients may become unconscious, but no patient has been observed in convulsions. The clinical picture is sufficiently alarming but the symptoms can be relieved very easily. Sugar will at once stop them, but orange-juice and hot tea or coffee will also relieve the subjective symptoms. In emergency a dose of adrenalin, 10 or 15 minims, seems to work instantaneously, but should be followed by a little sugar.

Wise and Foolish Patients.

E. P. Joslin, H. Gray, and H. F. Root report good results with 87 patients, and they emphasise the point that insulin is a remedy for the wise patient and not for the foolish one. The patients usually gained weight under treatment, and they raise the question whether this gain in weight is a sign of any recuperation of the pancreas. The results were equally good whatever the age of the patient. One girl, aged 12, who had only been ill 32 days made a rapid recovery. She had a normal fasting blood-sugar with only 3 units of insulin a day and was able to eat 155 g. carbohydrate. Joslin does not accept the view that the fasting blood-sugar must be brought down to normal at all hazards. He gives an excellent list of rules for patients, and one of the most important is "If your supply of insulin fails reduce your diet by one-third."

The Effects of Dextrose and Lævulose.

R. M. Wilder, W. M. Boothby, C. J. Barborka, H. D. Kitchen, and S. F. Adams report good results with 40 cases treated with insulin. As the insulin in the early stages was irregular in potency a scheme for its standardisation on patients was worked out. They found that if the protein of the diet was increased up to 3 g. per kilo, keeping the caloric and carbohydrate value of the diet constant, the insulin had less effect. Insulin would rapidly cause a patient who was losing nitrogen to gain nitrogen. They do not consider it essential to bring down the blood-sugar to normal.

The basal metabolic rate was unaffected by insulin. Experiments were made with equal amounts of dextrose and lævulose with and without insulin. Lævulose caused a small rise in the respiratory quotient (R.Q.), even when no insulin was given, while after insulin, although both caused an increase, that produced by lævulose was much greater. The specific dynamic action of the two sugars was equal, but the blood-sugar was less raised after lævulose. The authors suggest that the insulin brings the sugar into a reactive form which is more available for oxidation and polymerisation. Further, that it is the position of the C.O. group in lævulose which is responsible for the latter sugar being better used than dextrose. J. R. Williams reports the results of four cases, one of which was very severe. The results were very striking, but there was no sign of any recovery. He advises 2–3 injections a day as being less likely to cause severe reactions. He is doubtful whether the dose of insulin will not have to be increased. He also considers that the blood-sugar should be kept higher than is customary when no insulin is given. R. Fitz, W. P. Murphy, and S. B. Grant report observations on the R.Q. before and after insulin. They found that it rises considerably as the result of the insulin and does not fall again until some days after the insulin has been discontinued. The effect of insulin in bringing the patients into nitrogen equilibrium is very striking. The fasting value of the blood-sugar was above normal in their cases. H. Geyelin, G. Rawle-Harrop, M. F. Murray, and E. Corwin reproduced photographs of three children before and after treatment with insulin.[1] They show the striking improvement which takes place when sufficient food is given. The children all had high blood-sugars and passed sugar before the insulin injections. R. T. Woodyat thinks that it is better to give only one dose in the day. He does not consider that it is essential to aim at bringing the fasting blood-sugar down to normal. One profoundly under-nourished man developed hypoglycæmia after insulin, and although he was given sugar and had hyperglycæmia he did not regain consciousness.

Observations on 161 Patients.

F. M. Allen and J. W. Sherril publish a long account of their work on 161 patients, many of whom had been under observation for a long time. They have been treated on the lines familiar to those who know Allen's work. Certain facts stand out among the mass of detail. Allen believes that the aim of the physician should be so to use the insulin that the fasting blood-sugar should be normal. He gave three instances in which patients were treated on different lines, and shows the dangers of discontinuing the insulin suddenly. The three patients all became ill, but the symptoms of coma were very anomalous and would not have been detected unless the blood had been examined for sugar and acetone bodies. The authors do not think that it is possible in every case to bring the blood-sugar down to normal. Two of their conclusions deserve especial mention. "Insulin has tremendously improved diabetic treatment, but has not simplified it." Again, "Insulin . . . cannot atone for lax or inaccurate dietary methods."

A Defence of the Principle of Undernutrition.

In the first number of vol. iii. of the same journal J. W. Sherril continues the account of the work done in Allen's laboratory with a paper on the influence of carbohydrate and protein on diabetes and the insulin requirement. The diets of the patients were very carefully controlled and were changed in order to bring out special points. He concluded that carbohydrate had a stronger glycosuric effect, and required more insulin than any other kind of food when it was given in equal caloric value. Protein required much less insulin than carbohydrate when it was substituted for carbohydrate either in equal caloric equivalents or in equal carbohydrate content. It was also much less efficacious in the treatment of hypoglycæmia. Some of these results are rather surprising as it had been thought that the specific dynamic action of protein gave it special glycosuric properties. Sherril also concluded that there was no constant relation between insulin dosage and the carbohydrate intake, as it depended very largely on the caloric value of the diet. Allen discusses the influence of fat and total calories on diabetes and the insulin requirement. He opens with a long and able defence of the principle of undernutrition, and attacks the work of his critics, especially Woodyat, Newburgh, and Marsh. Numerous tables are given of diet experiments with insulin. An attempt was made to assess the total insulin requirements of a small girl of 3 years old. This child could only tolerate 100 calories without passing sugar, but with 3 units of insulin 400 calories were tolerated. It is suggested that her initial insulin production was about 1 unit and that she therefore needed 4 units altogether for that amount of food. The evil effects of a great increase in the body-weight due to a great increase in the caloric value are pointed out. In one case the dose of insulin was very large and had to be increased. When the diet was reduced the weight decreased and the dose of insulin could also be diminished. The effect of these facts is that the clinical condition is no longer a guide to the real condition of the patient being treated with insulin. Allen concludes that the principles on which the undernutrition treatment were built have been proved correct by his experiments with insulin. C. H. Best and D. A. Scott had been exploring the possible sources of insulin, and, stimulated in their search by the publication of Winter and Smith's work on the presence of an insulin-like substance in yeast, have been able to demonstrate a substance which lowers the blood-sugar of rabbits in potatoes, rice, wheat, beet-roots, and celery. Working with Banting they have also demonstrated an insulin-like substance in the blood of the ox, dog, rabbit, and man.

Results from Switzerland and Germany.

The *Schweizerische Medizinische Wochenschrift* dated August 30th contains two articles on insulin. Prof. H. Sahli, of Bern, gives a good account of the early work on the search for the internal secretion of the pancreas, paying special attention to that of Zülzer. The latter undoubtedly showed in 1907 that a pancreatic extract had considerable influence on the urine sugar of diabetic animals and patients, but the local symptoms following the injection were so unpleasant that the discovery attracted little attention, and was soon forgotten. Prof. Sahli proceeds to describe the physiological properties of insulin and its effects on patients with diabetes mellitus. He lays especial stress on the importance of combining the use of insulin with the usual dietetic treatment. He gives an account of the method which he has employed for mild and severe cases. If determination of the blood-sugar cannot be made, he thinks it is safer to allow the patient to excrete a little sugar, although he admits that this is not the ideal treatment. He also expresses the opinion that insulin is only a symptomatic treatment, and has no real healing process. But a vicious circle can be broken by its use, and in this sense it has a certain degree of curative value. Dr. M. Guggenheim, of Basel, also gives a good account of the past and present uses in discovering insulin, and of its physiological action and clinical effects. He considers that the amount of food and the dose of insulin should be so chosen that the fasting blood-sugar is within normal limits. A very large number of references is given.

In the *Deutsche Medizinische Wochenschrift*, of August 17th, Prof. W. Ercklentz gives an account of his treatment of six patients with insulin. The clinical results were very good. He also states that if blood-sugar determination cannot be made it is better to allow the patients to pass a little sugar. In the same journal (August 24th) Prof. O. Minkowski, who with von Mering was responsible for the original extirpation experiments on the pancreas, expresses his satisfaction with the properties of insulin. He gives an interesting account of the hindrance to the introduction of insulin into practice in Germany at the present time owing to the difficulties with the exchange and the bad financial conditions.

Standardisation of Insulin.

In "Public Health Reports" (August 3rd) Prof. Carl Voegtlin and Edith R. Dunn describe the difficulties of standardising insulin. They have used albino rats instead of rabbits, as being less expensive. The rats are kept on a constant diet. It was found necessary to keep the temperature of the chamber constant, as the rats were much more easily killed at a temperature of 28° to 30° C. than between 15° and 22° C.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH

THE following table gives some of the principal health statistics of a group of counties for 1922 :—

Name of county.	Estimated population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Respiratory with influenza.	Infant mortality		Maternal mort. from childbirth.
							Legit.	Illegit.	
Northamptonshire.. ..	213,340	18·1	11·7	0·9	1·4	1·8	58	77	5·2
Warwickshire..	348,003	21·2	11·0	0·8	1·0	2·2	(60)		5·0
Cambridgeshire	129,591	18·3	12·7	0·9	1·6	—	59	65	3·3
Cumberland ..	218,499	22·3	14·7	0·9	1·3	3·1	99	117	5·1
East Suffolk ..	207,424	19·5	12·6	1·1	—	—	(64)		—
West Suffolk ..	109,406	18·6	13·6	1·0	1·7	2·3	(55)		3·4
Fife	112,384 (extra-burghal)	22·4	12·6	0·8	1·1	2·5	(99)		6·0

The bracketed figures give the total infant mortality. Lines indicate that the information was not given in the report.

Northamptonshire.

Dr. Charles E. Paget reports that a special subcommittee of the county council is considering the coördination of health services but had not finished its deliberations at the end of the year. A move has been made in the direction of having a single small-pox hospital for some of the northern county districts. The Rushden House Sanatorium was opened in the fourth quarter of 1921 for early, middle, and advanced cases of pulmonary tuberculosis. The 50 beds retained for men, women, and children from the county remained full during 1922, but the 18 beds set aside for private patients and other authorities were not so utilised. Two of the latter were used for spinal cases, pending the provision for such cases at the Shropshire Orthopædic Hospital at Oswestry. Some progress has been made in the improvement of water-supplies, but the long delayed scheme for Thrapston is still only under consideration. Housing schemes have provided 530 new houses in 19 out of the 28 districts and private enterprise 90 new houses in 21 districts; but house shortage is acute in the Raunds, Rushden, Desborough, Irthlingborough, and Kettering urban districts and in the borough of Daventry. The veterinary inspection of cattle is proceeding satisfactorily in certain districts, and Dr. Paget hopes it will soon become general in the county. The public analyst reports that 19 of 335 milk samples were below the standard and 8 out of 47 samples of skimmed milk. In one milk 60 per cent. of the fat had been abstracted and in two cases 30 per cent. and 40 per cent. respectively of water had been added.

Dr. Lila S. Greig, in her maternity and child welfare report, shows that 51 per cent. of the births are attended by midwives. She points out the need that the doctor called in to a suspected septic case should give prompt instructions to the midwife. The midwives have been supplied with collosol argentum, but this practice is to be discontinued. It is not thought that the incidence or severity of ophthalmia neonatorum has been diminished by the use of collosol argentum and it has been used by midwives in some cases for treatment, causing a delay in notification. Out of 20 notifications, the sight of the left eye was lost in one case and in another the result is not known, these two cases being in doctors' practices. The other notified cases made a good recovery. Dr. Greig mentions that among the notifications required of the midwives that with regard to artificial feeding is the most neglected. Out of 74 infants reported by the midwives at the end of the year to be artificially fed, only 28 had been notified by them at the proper time. The percentage of breast feeding reached 73·7 per cent. in 1919 but has since declined and was 65·5 per cent. in 1922. Health visiting in the Brackley area is carried out by the Northamptonshire District Nursing Association. Up to September this work was supervised by Dr. Greig, but from that date till the end of the agreement the special subcommittee, mentioned at the outset, has arranged for the work to be supervised by the superintendent of nurses. A report will be furnished to the subcommittee at the end of the period covered by the agreement.

Warwickshire.

Dr. A. Hamilton Wood deals with the pollution of the Rivers Tame, Anker, and Avon. The Tame is already polluted by the Black Country towns before it reaches Warwickshire and steps are being taken to minimise this. Inside the county the Birmingham, Tame, and Rea Drainage Board are carrying out experiments and improvements. As regards the Anker, the Nuneaton Council has converted old contact beds into percolating filters to keep back the excess of suspended matter appearing in their effluent and propose to lay down additional circular filter beds. It is hoped, too, that a satisfactory method has been decided upon for dealing with the long existing nuisance from the trade waste of the Sketchley Dye Works. The Avon is chiefly polluted by Rugby and Coventry. Rugby needs an extension of its filters but their proposed scheme has been restricted by the Ministry. Coventry has been experimenting for two years with bio-aeration (the method worked out at Sheffield), and proposes to apply this method to a daily flow of 3 million gallons at present imperfectly treated by irrigation. The new scheme of the Ministry of Pensions for the vocational training of ex-Service men suffering from tuberculosis is mentioned and it is pointed out that there is apparently insufficient accommodation at the training centres. In Warwickshire 17 men were examined in the summer of 1922, and six were passed as clinically suitable. Of these six, four were still waiting for vacancies in January, 1923.

Dr. Wood complains of the incomplete notification of births and suggests that it may be partly due to deliveries being conducted by handywomen who are afraid to notify. Of 7373 births, 505 were not notified. The mortality from puerperal fever was the highest ever recorded in the county. Dr. Wood also refers to the large number of still-births and does not see much likelihood of improvement till the practice of midwifery is given a higher place. In view of the many problems worthy of careful study which confront the accoucheur and the fact that midwifery deals with the ante-natal, natal, and post-natal states, he thinks that midwifery should rank in importance with other specialised branches of medicine "and not be left in the haphazard hands of the rank and file of the profession." The excellent system of voluntary infant welfare centres run in coöperation with the county council's scheme continues to develop. There are now 29 centres throughout the county. Three new centres were organised during the year, in spite of the fact that no grant from the Ministry is available for this extension; they are financed entirely by voluntary funds. The amount available for free milk has been made to go further by limiting the amount granted to each household (except in the case of bottle-fed twins) to one pint of fresh milk daily or three packets of dried milk fortnightly. Dr. Wood thinks notification of ophthalmia neonatorum should be made direct to the county medical officer of health, but he is in the happy position of recording that of 59 notified cases of this disease, all recovered with vision unimpaired.

Cambridgeshire.

Dr. Frank Robinson's report shows that much attention is given to the question of the midwifery and nursing service both in the county and borough of Cambridge. Through the agency of the County Nursing Association the number of trained midwives has increased since 1916 from 24 to 50. There are now only four untrained midwives. All the trained midwives practising in rural areas are also district nurses. During 1922 three grants were made to the County Nursing Association for the training of nurse-midwives who have to undertake to practice for three years in the county after becoming qualified. Through the County Association three new district nursing associations covering ten parishes were started during the year. Grants are also made by the county council towards the expenses of some of these district associations in employing nurse-midwives. Since the passing of the Midwives Act, 1918, the proportion of cases in which the midwives summon medical aid has gone up from 5·2 per cent. in 1919 to 7·2 and 7·1 per cent. respectively in 1921 and 1922. Of the 152 cases in which a doctor was called in during 1922, the county council paid the fee in 102 cases but, wherever possible, the fee is recovered from the patient in whole or in part. The borough has its own maternity and child welfare scheme, and under this scheme 139 expectant or nursing mothers received dental treatment, of whom 58 were provided with artificial dentures, one condition being that they agree to their children receiving dental treatment both up to 5 years of age and during the whole of their school life. Some progress has been made in housing matters, but Dr. Robinson estimates that some 600 or 700 new houses are still required in the county, apart from new houses needed to replace worn-out property. The severe drought of 1921 stimulated the provision of schemes of water-supply, and progress in this direction is reported.

Cumberland.

Dr. F. H. Morison is inclined to attribute the great increase in infant mortality to unemployment and the resulting inadequacy, especially as regards vitamins, of the diet of a large section of the community. The districts which showed the highest rates were those where there was most distress—viz., Cleaton Moor, 166; Whitehaven, 160; Workington, 127; and Egremont, 121. Dr. Morison returns to the food question in speaking of the prevention of tuberculosis, and expresses his belief that education of the community in food values would constitute one of the most valuable public health campaigns. He thinks we should do as is done in the case of quack medicines and proprietary articles—i.e., we should repeat our teaching until everyone is convinced that what is repeated so often must be true. He thinks the two most hopeful methods of dealing with tuberculosis are segregation of advanced cases and raising the resistance of those who are most susceptible, such as contacts, debilitated, and so-called pre-tuberculous children. He suggests that the Industrial School at Cockermouth, at present disused, might be used with the latter object as a preventorium for debilitated children. Returning to the subject of the high infant mortality rate, Dr. Morison points out that "at the present time there are no maternity and child welfare centres in the county with the exception of the one at Wigton, which is worked by the Wigton District Nursing Association."

The medical superintendent of the Englethwaite Industrial Colony for Consumptives, Dr. Mark S. Fraser, reports that of 79 men who received treatment and training and left during the last three years 23 are earning their living. Of the 23, 16 are in receipt of a modified pension and it is impossible to say if they would be able to maintain their families without this subsidy. Eleven of the 23 are working at trades learned at the colony. Dr. Fraser has seen most of them and finds that their health and working capacity are not nearly so good as those of the seven ex-colonists who are employed at Englethwaite. In consequence letters have been addressed to the sanitary authorities concerned asking them to establish after-care committees to befriend ex-colonists belonging to their own areas.

East Suffolk.

Dr. G. I. T. Stewart points out that for railway and other reasons the problem of locomotion is a difficult one in East Suffolk, and that the formation of combined districts with whole-time medical officers is not easy. Hospital accommodation is "lamentably deficient," and for this coöperation is the remedy. Dr. Stewart suggests a scheme for four areas based on an adequate motor ambulance service: (1) southern area—hospital at Ipswich and Felixstowe; (2) north-western area—hospital at Stowmarket (West Suffolk to be asked to join); (3) north-eastern area—hospital at Lowestoft; (4) central area—to be provided for by a county hospital at Saxmundham. The V.D. work is done at Ipswich and Norwich, but a clinic is needed at Lowestoft. The inspection of midwives is carried out by the superintendent of the Suffolk County Nursing Association. Lowestoft has its own child welfare scheme. Otherwise there is little to record in the way of "centre" work. There are three one-day-per-week centres at Aldeburgh, Beccles, and Stowmarket with average attendance of 6, 15, and 17 respectively, and centres started at Felixstowe, Leiston, and Wickham Market have closed down owing to lack of interest.

West Suffolk.

Dr. A. H. Bygott reports that the proposal to form the sanitary areas of the county into two combined districts, each with its whole-time medical officer of health, has been rejected by a meeting of representatives. An alternative was the adoption of the Essex system, but only four of the district medical officers of health hold the diploma of public health. The Bury St. Edmunds administrative bodies have expressed dissatisfaction that more is not done for advanced cases of tuberculosis. Dr. Bygott points out that one cannot establish "homes for the dying," that the county sanatorium has raised its beds to the maximum, and that the fever hospitals in the county are not suitable for the purpose. The county council were prepared to take over the infirmary of the Bury St. Edmunds guardians. The Ministry of Health suggested the Mildenhall Workhouse, but its inaccessibility and the cost of adaptation and administration ruled it out. A more effectual remedy, says Dr. Bygott, is for the county and county borough councils to take over the treatment of the sick from the boards of guardians.

Fife.

Dr. G. Pratt Yule says measles, whooping-cough, and respiratory disease have played their part in the increased infantile mortality of 1922, and refers to overcrowding as the determining factor in the fatality of these diseases. In some areas housing schemes, aided by emigrations to the Colonies and U.S.A., have relieved the situation, but among the more busy mining communities there is much subletting which is tantamount to overcrowding. A large shelter has been fitted up with 16 cots for the treatment of surgical tuberculosis in children at the Glenlomond Sanatorium. Cases of pulmonary tuberculosis are being reported earlier, and male cases are accepting institutional treatment at an earlier and more hopeful stage.

Dr. Yule refers to the "handywoman" difficulty. Not infrequently, he says, unqualified women appear to be the sole attendants at confinements, but when investigation takes place there emerges "the shadowy supervision of a medical practitioner." Dr. Yule has written to the C.M.B. for Scotland for guidance as to what constitutes "direction" on the part of a medical practitioner, but so far no light has been forthcoming. He mentions that the Royal Sanitary Institute and the County Councils' Association have approached the C.M.B. for England on the same point, and that the English Board are of opinion that "under the direction of" means "in the presence and under the direction of" and further, that they (the English Board) intend to take the earliest opportunity of pressing for an amendment of the subsection of the Act dealing with the matter which will remove the words "habitually and for gain"—words which render the subsection futile at present.

CANCER AND DIET.

To the Editor of THE LANCET.

SIR,—Your leading article under the above title in THE LANCET for last week obviously necessitates a reply from me.

Needless to say, no one can regret more than I myself the "flamboyant" and unwarranted statements that appeared in a certain section of the public press in reference to my paper in the Physiological Section at the recent meeting of the British Association. And I specially regret that your criticism of my communication should have been based on unsatisfactory reports. Rationing in this country during the last year of the war was fairly stringent, in the large towns at any rate, this stringency having been specially marked as regards those foodstuffs which, as you state, provide the main part of the fat-soluble vitamin A in a normal dietary. And yet, except as regards tuberculosis, there is, so far as I am aware, little evidence that the public health was adversely affected; while, as indicated by the Registrar-General's statistics, the cancer mortality for both sexes, especially in London, was slightly though definitely diminished. In the case of the Central European States to which you allude additional factors came into operation.

My own investigation as to the results of a dietary deficient in the fat-soluble A factor but sufficient (and this is the important point) in every other respect, while at the same time varied and appetising in character, has now extended over a considerable period,[1] and has included an experience of it in my own person lasting for nearly a couple of years. During this time I was necessarily engaged in a certain amount of physical as well as mental work. Yet it was not until the end of that period that I experienced any noticeable ill-effect as the result of the experiment—a skin affection of the palms of both hands which readily cleared up on the addition to my dietary of uncooked vegetable food in the form of salads. And Dr. Wyard,[2] reporting on our investigation at the Cancer Hospital, which you quote, stated in reference to patients on this dietary that "In no case was any unfavourable change in the general condition of the patient attributable to the diet, and in many improvement was definite, at least at first." The medical superintendents of several infirmaries in which patients have also been under treatment have reported to the like effect. The suggestion that I have overlooked the literature of the subject, and, more particularly, the work of Prof. J. C. Drummond, is hardly borne out by the fact that in my paper I specifically referred to his investigations and, as regards the growth of tumours, stated that I was in general agreement with his views.

The second paragraph of the article would seem to be superfluous in view of the fact that in my paper I stated that the use of the dietary had not been found to exert any specific differential effect on the growth of the tumour, as had originally been hoped might prove to be the case; and that consequently the cure of cancer was not in question, the methods being at most palliative only. As regards this latter point, it may be noted that Dr. Wyard in the report you quote makes the statement that "general improvement, though slight, was in some instances definite." It may be mentioned that estimates as to probable prolongation of life in any instance have necessarily been based on the opinion of those in medical charge of the patients as the outcome of their general experience of cases in similar condition.

As regards the final paragraph, I may perhaps be permitted to state that a few months ago I submitted to a meeting held in the laboratories of the Imperial Cancer Research Fund, under the chairmanship of Dr. Murray the Director, a communication practically identical in terms with my Liverpool address. This meeting, at which Dr. Wyard was also present, afforded opportunity for helpful criticism. The dietary in question has been gradually evolved as the outcome of consultations with Prof. Gowland Hopkins and other bio-chemists; of experiments on myself, and, with their consent, on other private individuals, and of patients in various public institutions; as also of a comparative study (not yet completed) of the dietaries and vital statistics of certain "enclosed" and "unenclosed" religious communities in this country and abroad.

It is, I think, unnecessary to comment on the assumption with which the article concludes.

I am, Sir, yours faithfully,

Sept. 24th, 1923. S. MONCKTON COPEMAN.

PROBABILITY AND EXTRASENSORIAL CHANNELS OF KNOWLEDGE.

To the Editor of THE LANCET.

SIR,—In his address on Extrasensorial Channels of Knowledge (THE LANCET, Sept. 8th), Prof. Charles Richet brings forward evidence which, in his opinion, establishes the truth of "knowledge of reality obtained by other means than by the ordinary channels of the senses." Some of this evidence is of the following character. A dreams that B, of whose movements he can have no direct means of information, has died, and, in fact, B *has* died. To the retort of the man in the street that this is a mere coincidence, Prof. Richet replies: "Chance is, indeed, a very convenient god, to which we can always appeal. But why should we introduce these extremely small probabilities into our calculations? Practically we never come across a probability of 1 to a 100 million, and yet this is the figure at which one must assess the probability of Wingfield having once in the course of his life a single hallucination, and that just the hallucination of his brother being killed at the same moment. Chance will evidently not explain these occurrences." I do not know how it is possible to assess the arithmetical value of the probability in Wingfield's case, since I have no knowledge of the frequency or contents of this gentleman's dreams, save in one instance, but the man in the street would surely rejoin that, far from never coming across probabilities of 1 in 100 millions, he meets them almost every evening. The probability that the dealer at bridge will distribute the 52 cards in any assigned order is measured by a fraction which has more than 60 zeros after the decimal point before we reach a significant figure, it is the reciprocal of the continued product of 52 × 51 × 50, &c. Events, the probability of which is so immensely less than Prof. Richet's 1 in 100 millions, happen regularly wherever four bridge players are gathered together. Evidently there is something wrong. The philosophy of the calculus of probabilities has engaged the attention of many eminent men and they have made such sad mistakes, according to Mr. J. M. Keynes, that it is dangerous for a mere statistician to suggest an explanation; but, as the use of probabilities is very common in medical inquiries and so distinguished a physiologist as Prof. Richet has employed that calculus, it may be of interest to play the devil's advocate and to argue that Prof. Richet's treatment of his problem is wholly fallacious.

---

[1] Copeman, S. M.: Brit. Med. Jour., 1920, ii., 159, Discussion on the Present Position of Vitamines in Clinical Medicine.

[2] Wyard, Stanley: THE LANCET, 1922, i., 840.

The point I submit is, that in any rational application of the calculus of probabilities there is always expressed or implied an alternative. Thus suppose four persons sit down to play bridge and the dealer receives the whole of a particular suit. The chance that this will happen is much less than one in a billion, a good deal smaller than one in 100 millions. Suppose the four players are intimate friends, they may be surprised, they may even write to the *Field*, but they will not suspect the dealer of cheating. But suppose that the four players are total strangers come together in the smoking room of a transatlantic liner, the opponents of the dealer who has dealt himself or partner 13 of a suit might do more than write to the *Field*. The point is that the alternatives in the two cases are not deemed to be equally probable. The probability that an intimate friend has cheated at cards is deemed to be very much less than 1 in a billion, but the probability that a total stranger has cheated is thought greater than that a particular event of this order of frequency *and favourable to him* has happened.

Consider the method of application of the calculus of probabilities to medical problems, usually regarded as legitimate. A persons have been attacked by a disease and treated with a particular remedy and a have recovered, B persons similarly attacked have not been treated and b have recovered. The fraction a/A is greater than the fraction b/B; is the difference significant? Let us suppose, which is *not* always true, that A and B are, apart from the giving or withholding the remedy, absolutely *in pari materia*, and that the probability that such a difference as $a/A - b/B$ might arise "by chance" can be arithmetically computed—which again is not always true—and that we find this chance to be 1 in a billion, what is the inference? The inference depends upon the nature of the alternative. If the remedy is such that its *possible* activity is not incongruent with the whole of our knowledge, we shall infer that it is more likely that the remedy had an effect than that an event which on the average happens once in a billion trials has happened this time. Suppose the disease were acute intestinal obstruction and the remedy painting the left wrist with iodine; we should refuse to believe that the cases were *in pari materia* or we should adopt the attitude of the friendly bridge players. Suppose the disease were diphtheria and the remedy antitoxin, we should unhestiatingly accept the alternative. Between those extreme terms lies a continuous series of instances; the mere statement of a probability is not and never can be sufficient of itself, it is only great or small in relation to something else. That is, of course, the argument of Hume—stated before his time by Locke, who said, "It is harder to believe that God should alter or put out of its ordinary course some phenomenon of the great world for once, and make things act contrary to their ordinary rule purposely, that the mind of man might do so always after, than that this is some fallacy or natural effect of which he knows not the cause, let it look ever so strange."

I need not use space to point out the application of these considerations to Prof. Richet's thesis, but those who are interested in the particular class of investigations to which he refers will find a very instructive discussion of the application to them of the calculus of probability in Prof. Edgeworth's notice [1] of Prof. John Coover's investigations.

I am, Sir, yours faithfully,
MAJOR GREENWOOD.

A PLEA FOR THE NATIONALISATION OF OUR MENTAL HOSPITALS.

To the Editor of THE LANCET.

SIR,—It is not until quite recently that the attention of the medical profession, and to a certain extent of the general public, has been at all directed to the position of the treatment of disorders of the mind. Probably owing to their extreme complexity it has remained more or less in the background. No attempt has been made on anything but the smallest scale to apply the same methods of investigation and treatment which mark other branches of medical science. As a result the insane have been merely herded together in public institutions really more concerned with the safeguarding of the public than with alleviating the sufferer. Reform on these lines has merely meant a more humane segregation, with the result that scattered all over the country we find these large buildings, for the most part admirably and economically administered, where the insane are housed and fed while they may or may not recover. What position these institutions hold in the opinion of the outside public is clearly shown by the fact that practically all admissions to them are involuntary. Nowhere is there yet set up a system where the early sufferer will come for advice and treatment in the same way that he will flock to the ordinary out-patient department of any of our large hospitals.

But at last the mystery attached to the label "mental" is gradually being solved and removed. It is recognised that for the best results cases must be seen in their incidence. Also that disorder of the mind requires not only the specialist trained in psychological methods, but the help of the pathologist and the physician, in fact of every branch of the profession. And not only this, but equally important is skilled nursing of the very highest order. With what result? That the treatment and study of mental diseases is passing to the place where only these advantages can be reaped—into relation with our general hospitals and teaching centres. For if, say, a case of cardiac disorder or a fracture turns out badly, the patient can still carry on under a partial disablement; but let a disorder of the mind become chronic and it results in a complete failure and a permanent loss to the State. It is quite impossible and also unnecessary to alter our present asylums and make them into hospitals suitable for the reception and treatment of acute mental disorders; and equally impossible for the large bulk of their present medical staffs to keep themselves abreast of modern methods. And neither is this the most economical method. It is waste of time, money, and personnel to employ a highly trained staff on the nursing of idiots, dements, and the hopelessly insane. Having regard for the treatment they require, we can divide our patients roughly into two classes: in the early stages, when everything that our science can possibly do for our patient must be tried; if this fails in its end and no recovery takes place, we pass to the second, the chronic or hopelessly insane, requiring merely some institution where they can be looked after as economically as possible with due regard to their happiness, comfort, and welfare, and where they can be employed to the best advantage with regard to their cost of maintenance and by this means made the least possible burden to the State.

Now arises the problem, how can early mental disease be brought into contact with the conditions it requires for its treatment? It is impossible to think that under present conditions this will ever maintain in the majority of our county or borough asylums. Their isolated position alone is almost a bar to most of them. Neither ought the matter to remain in statu quo until the country can stand the enormous expense of building and equipping new and modern mental wards. In the meantime there is one obvious way in which the best can be done for the sufferer. It is out of the question that every case of mental disorder can be sent for treatment to one or other of our great teaching centres. But why not bring a recent product of this centre to him? A constant supply of skilled physicians, au fait with every advance in the diagnosis and treatment of mental diseases, must be supplied to all our county and borough asylums. Not to one or two of them, but to every one in which early acute cases are admitted. Present buildings cannot be altered, neither can their inaccessibility; but at least they can be supplied with a staff of the highest efficiency, who will do their best in the conditions under which they have to work to apply for the benefit of those under their care the methods of investigation and treatment emanating from our hospitals and universities. And this can only be brought about by nationalising the whole asylum service and bringing it under one central control.

Let us consider such a service a little in detail. It should most certainly come under the Ministry of Health, and the nucleus of its special control, or "G.H.Q. asylums," already exists in the present members of the Board of Control. At present this Board has no control, or practically none, except perhaps from a legal point of view. But under a national scheme it would own completely all asylums at present designated "pauper." It could introduce what reforms it wished, appoint the various resident staffs, and its visiting consultants could take with them into town and country a knowledge of the most recent methods of investigation and treatment, to place at the disposal of the resident staffs. For who has not served as house surgeon or later as divisional officer and does not appreciate how such visits keep a man up to the scratch? And how much better employed would skilled physicians be going over our recent admissions with us, teaching us and advising our actual treatment, than writing reports recommending a more general use of toothbrushes in such and such institution, or saying how nice the patients' dresses looked. In the same way there would exist at the Board of Control a department corresponding to that of the Quartermaster-General. These gentlemen would standardise everything in use, from dress material to medical stores, and would distribute them as in the army from a central depot or depots. Some commodities it would conceivably be cheaper to purchase locally. They would appoint the officers, and visit, inspect, and control the departments at present known as "stores," "farm," "clerk of works," "accounts," and even the padre. Corresponding members of asylum staffs would constitute a "service" just as would the medical side, and would reap the same benefits.

There would be an entrance examination, standardised pay, promotion, and pension. Examinations qualifying for promotion to a higher grade in the service would have to be passed before any step upwards, and most important, "movement orders" would be issued by the Board of Control. In this way all medical officers would periodically and regularly pass through one or other of our teaching centres as a part of their duty; there would be none of the present farcical method of appointment, and no one would be left out in the cold to rusticate and become a typical "chronic" to his own detriment and that of the patients under his care. Anyone failing to qualify for promotion would not be kept in the service but the right men would get to the top. It is the staffing of hospitals where actual treatment of recent cases is being undertaken which calls for the highest efficiency. To these would be supplied the young, active, progressive, and best qualified members of the service. Senior members would eventually be automatically moved either to fill purely administrative posts, or to the essentially chronic buildings where wise and economic administration is the main asset; and where their experience and foresight can be used to the best advantage of the service as a whole. The nursing service would be similarly constituted. Each institution would have a definite establishment, promotion to positions corresponding to N.C.O.'s would all have to go through G.H.Q. before being confirmed, recruiting locally for the junior posts, or "privates" if necessary.

The entire cost would be taken off the shoulders of local authorities and would become a common universal Government tax. The total expenditure of all our county and borough asylums for the year 1921 was under 8 million pounds, about the cost of one modern battleship, very little to pay when the importance of the question is realised. For the Government to take over its mental hospitals means no new expense, but merely a transference from a local rate to a national tax. A single control is absolutely necessary to prevent overlapping and to ensure economy and efficiency. Present institutions can then at once be used to the best advantage of the service, and not as at present, merely for local requirements. Some would be used solely for the chronically insane, on whom it is a waste of money and personnel to employ a highly skilled staff. Empty beds in these institutions can always be filled by segregating patients with no friends. Others could be specialised into convalescing hospitals, where patients on the way to recovery can be sent to reap the benefit of outdoor occupation; this in turn easing the demand for accommodation in the acute blocks. Of two more or less adjacent buildings, the one more easily adaptable and more accessible for a visiting staff could be used as the acute building for the reception of new cases, the other becoming essentially chronic in character and therefore needing no modernising and no highly skilled staff. It would seem that by wise administration the general lunacy tax should be appreciably less than the present average county or borough maintenance rate.

The patient, and a medical staff with the necessary training and skill, are brought into contact near to the former's home and friends. Beds for the early treatment of cases can be subsidised by the Government in some of our large general hospitals, out-patient departments set up and the best advice brought within the reach of all. Not only the patients' treatment, but their food, clothing, occupations, and amusements would be uniform and the best available. The present farcical investment of a lay committee with practically the sole right of discharge would depart into the waste paper basket. This power would be invested in the medical superintendent, at whose disposal in difficult cases would be the advice of the whole of the consulting staff of the service. A patient could receive his discharge as soon as fit and not have to wait for monthly meetings. And so it comes about that the very best of advice and treatment is placed at the disposal of the poorest; a state of affairs which maintains also in every other branch of our profession.

It would be up to each private mental hospital for the reception and treatment of acute mental disorders to put its house in order; the entire cost of which, of course, they themselves would have to shoulder. There could exist no possible bar to the present practice persisting of private patients being received into Government institutions. Provided, of course, that such buildings were deemed by the Board of Control as suitable for the class of case received, and that the charges, depending on the advantages and conditions offered, were privately borne. This paper is written in no attitude of criticism, nor does it pretend to have solved more than a very few of the difficulties, but rather in a spirit of hope that this important matter may soon be taken up. There is no money available in the country for expensive new buildings. Meanwhile, the problem is to make the best out of what we have actually got. How to tackle the task, so that as speedily as possible, an efficient service can be brought about with as little waste and as little disturbance as is absolutely necessary. At present, for obvious reasons, Smith who goes insane in "Blanktown" may receive every advantage and chance of recovery for 20*s.* a week; whereas Brown, because he happens to be domiciled in "Muddleshire," starts with a 30 per cent. disadvantage at perhaps half a crown a week cheaper. The brains of a country are its most important asset and should be the first charge on its estate. The present standard of the treatment of the insane as a whole is many years out of date. To bring that standard on to a level with that reached in any other of the ills that flesh is heir to, is a national affair, a matter of vital importance to future generations and to the race as a whole. It is surely up to the nation to take the matter in hand and to shoulder its responsibility, for private enterprise must inevitably fail. There must be some central controlling and guiding authority. Run something on these lines it would make a most attractive service. Not only will it attract good men into its own special branch, but it can utilise and bring the best brains in all branches of the profession as a whole, to bear on to the most difficult and abstruse of all medical problems. Difficulties there will be, but they can all be got over, and fortunate will be those privileged to assist in working out the scheme and to see it actually working. For come it will.

I am, Sir, yours faithfully,
A. T. W. FORRESTER, M.D. Lond.

Leicestershire and Rutland Mental Hospital,
Narborough, Sept. 18th, 1923.

INJURY AND DISEASES OF THE ARTICULATIONS.

To the Editor of THE LANCET.

SIR,—Mr. Timbrell Fisher is greatly to be congratulated on his research work in that very difficult field of physiology, the articulations, of which he gave a brief résumé in your issue of Sept. 15th. In discussing treatment, Mr. Fisher suggests that in many sufferers from arthritic disease of non-tubercular origin the infection has come to an end and that the whole of the symptoms are caused by the deformity, and he further implies that in this stage of the disease manipulative and presumably operative methods can be undertaken with a certain degree of safety, provided that too much force is not used in manipulating the affected joints. Mr. Fisher goes on to say that forcible manipulation is not advisable in the more acute forms, as it may give rise to a reaction after which the joint stiffens once more.

I would like to make it axiomatic in dealing with these conditions that until the disease is extinct—that is to say, until the infection is eradicated and there is no longer any risk of auto-inoculation—nothing forcible of any kind whatever must be done. I would add that manipulation may do a great deal of harm, because it may result in the spread of the disease into other parts of the body hitherto unaffected. The converse of this axiom is also true: once the infection is eradicated, any measures, manipulative or operative, can be undertaken with perfect safety. I base these conclusions on some 15 or 16 occasions when operative or manipulative measures were undertaken. Of these all have been successful except four. One of the four was a patient who, unfortunately, died from alcoholic delirium a few days after the operation. I have no reason to suppose that it would not have been successful. In the case of the other three, the operations were undertaken before the disease was eradicated, and the result was that some extension of the disease took place, and there was a long period of convalescence before anything further of this nature could be done. In one case three years, in another case six months, and in the third case not at all.

But it may be asked by what signs we may know that the infection is eradicated. This is a question of the greatest importance on which one would like to hear Mr. Fisher's views. All the patients in my care have undergone a course of vaccine treatment, and the antigens in every case have been streptococci, either stock or autogenous or both, and in the majority of cases *M. deformans*. My experience shows that as long as the patient is sensitive to small doses of these vaccines, it is neither safe to manipulate nor operate. But as soon as the patient can take large doses without any reaction, both are absolutely safe. Thus the three cases above-mentioned in which manipulation or operation failed were still sensitive to quite small doses—e.g., half to one million—whereas the whole of the successful cases took large doses, more than 20 million without reaction.

The criterion I would suggest then is the absence of response to a large dose of an appropriate vaccine. When, however, we consider the question of what that dose should be, some difficulty arises. It appears that vaccines prepared in different laboratories differ materially. I am quite ready to make a definite statement in regard to the correct "safety" dose of the vaccines I use, made in my own laboratory, and would put it at 20 million combined stock streptococci and *M. deformans*. But then my initial dose is one-tenth of a million, either of streptococci or *M. deformans*, and even this frequently cannot be tolerated previous to a course of desensitising peptone; whereas doses of streptococcal vaccine recommended by clinical laboratories and given by other men are usually far larger. Compare this initial dose with that of five million advocated by Dr. W. H. Wynne, for example, in your issue of Sept. 22nd. The reason of the discrepancy I do not know, unless it lies in the fact that 45 perfectly different varieties of streptococci comprise this stock vaccine and all were freshly isolated.

I am, Sir, yours faithfully,
Harrogate, Sept. 22nd, 1923. H. WARREN CROWE.

THE CAUSATION AND TREATMENT OF PRURITUS ANI.

To the Editor of THE LANCET.

SIR,—Pruritus ani is very common, and its causation appears to be wrapped in obscurity; its treatment, therefore, is naturally unsatisfactory. As Dr. E. F. Hoyt of New York has said, "the meagre literature upon this subject hobbles upon the crutches of hypothetical inferences which suggest a panoramic array of medical agencies, all unsatisfactory, and thereby confessing to a sad condition of helpless empiricism." Having been a sufferer from this complaint off and on for 34 years, it has occurred to me that my personal experience with regard to its treatment may be of value to those who have cases of this sort. I found that relief could always be obtained by getting out of bed as soon as one was roused by the itching, and after evacuation of the irritating mucus by straining, by free washing of the everted mucous membrane with cold water. This usually produced a quiet condition for the rest of the night. Then I found a collapsible tube of carbolic vaseline about ♏ ix. to 1 oz. of use; a little applied to the anus and into the bowel immediately before going to bed enabled me to get to sleep without the onset of the itching which otherwise seemed invariably to occur as soon as I tried to compose myself to sleep. For years I slept with a tube of this vaseline by my bed, and if I woke in the night I always applied a little of the ointment and so repressed the inclination to scratch.

About 24 years ago I consulted Sir Charles (then Mr.) Gordon-Watson. He held the view that the cause of this trouble lies in the papillæ of Morgagni, which, situated at the anorectal junction, are absent in the majority, yet present in a considerable proportion of individuals. They are normally small white glistening papillæ, pyramidal or triangular, with the apices directed upwards and inwards towards the lumen of the gut. They vary from one to six, and when hypertrophied resemble in size and shape the writing end of an ordinary lead pencil; when much hypertrophied they may be felt as small shotty nodules. In some cases one finds small fibrous branched papillæ as well; and I think it is advisable to destroy these also as they may possibly be an additional source of irritation. Dr. Campbell Margarey wrote a paper on this subject several years ago in the *British Medical Journal*, from which I quote freely. He examined 50 out-patients with the speculum and as far as possible in consecutive order. In this series papillæ were present in 19 cases, or 38 per cent. The average age was 39 and of those in which papillæ were found was 38 years. The number of papillæ varied from one to six, with an average of two. In a series of patients suffering from pruritus ani attending the out-patient department from June to November, 1910, hypertrophied papillæ were present in 13, or 25 per cent. The papillæ were cauterised more or less thoroughly in all these cases, and in only one was there a lack of improvement. The majority made two subsequent attendances, reporting great relief, and then ceased to attend. This would serve to show that the cure of this exasperating complaint had been effected. In my own case Sir Charles Gordon-Watson destroyed these hypertrophied papillæ with the electric cautery. This was done without even a local analgesic and was not very painful. The itching, which had become unbearable, disappeared at once like magic, and I remained absolutely free for about five years. There was then a slight return occasionally, but carbolic vaseline kept it in check. About a year ago, as the pruritus had again become rather troublesome, I was examined by a surgeon, having first told him what he would probably find. He destroyed five or six papillæ with instantaneous results, and has since treated four similar cases with equally good effects. The reappearance of a papilla is in my case always attended by a return of the pruritus and discharge of irritating mucus which rapidly causes the skin to inflame.

It is possible for the patient accurately to locate by his own sensations the position of the papilla—e.g., at 6–9–10 o'clock—and in this way he can guide the operator as to where to look for it. If the skin be excessively sensitive and the sphincters very irritable, a little ½ per cent. novocain solution may be injected into the sphincters so as to cause their paralysis and allow of free exposure of the affected area. In one of our cases spinal analgesia was resorted to on account of the extreme excoriation and sensibility of the parts. The patient should be warned that the papillæ are likely to recur, and advised to return for their destruction immediately any fresh itching is felt.

I am, Sir, yours faithfully,

F. J. W. PORTER,
Bombay. Major, R.A.M.C. (retd.)

THE MILNE TREATMENT OF SCARLET FEVER.

To the Editor of THE LANCET.

SIR,—The article by Dr. G. Gushue-Taylor in your issue of Sept. 8th on the Treatment of Scarlet Fever by Eucalyptus Oil and Carbolic Oil versus Isolation is a convincing demonstration of the futility of the treatment which has become associated with the name of its originator. What can be said of a method which, in the hands of the late Dr. Milne himself, produced a "return" case-rate of 46 per cent.? What would be said of any isolation hospital which produced any such a percentage of "return" cases of scarlet fever? The figures show that in 1904–5 cases treated by Dr. Milne by isolation gave a return case-rate of 1·2 per cent.

In 1918 cases treated by Dr. Milne by the Milne method—return case-rate 46 per cent.

In 1921 cases treated by Dr. Gushue-Taylor by the Milne method—return case-rate 28·2 per cent.

In 1922 cases treated by Dr. Gushue-Taylor by isolation—return case-rate 3·7 per cent.

There are two criticisms of the so-called Milne treatment. 1. It is prima facie unscientific. One could not expect any satisfactory sterilisation of the pharynx to be effected by the methods proposed. Further, scarlet fever is not spread by the skin, therefore the treatment with eucalyptus oil is a redundancy. 2. It has now been proved by an investigation lasting over 18 years that in practice it does not work. It is desirable to call attention to the article as some medical officers in search of a cheaper and more satisfactory method of dealing with scarlet fever than hospital isolation have sought to find it in the Milne method. Many cases of scarlet fever can be nursed at home, but the Milne treatment is of no assistance in preventing the dissemination of the disease or in lessening its complications.

I am, Sir, yours faithfully,

A. H. G. BURTON,
Sept. 18th, 1923. Medical Officer of Health, Ilford.

Obituary.

MARGARET BOILEAU, M.B., B.S. LOND.

THE death of Dr. Margaret Boileau on Sept. 17th at Norwich removes an interesting personality from the ranks of medical women. Born in 1867, Dr. Boileau qualified M.B., B.S. Lond. in 1906 from the London (R.F.H.) School of Medicine for Women, having taken up the study of medicine preparatory to devoting herself to social and religious work. After working as clinical assistant to out-patients at the Elizabeth Garrett Anderson Hospital she started a general practice in Hammersmith, but for family reasons she was obliged to give up her medical work and return to her home at Ketteringham, in Norfolk. Here she engaged in social and medical activities, giving lectures on physiology to missions, lectures on venereal diseases, first-aid and Red Cross lectures, and assisting at an infant welfare clinic at Norwich. During the war Dr. Boileau became commandant of the Swainsthorpe Auxiliary to the Norfolk and Norwich Hospital and her work was specially commended. She was also Commissioner of Girl Guides for South Norfolk, and was elected as lay representative on the House of Laity, being one of the first women to hold this position.

Dr. Boileau will be much missed in Norfolk. Having an unusual faculty for explaining scientific truths in a clear and simple manner, her talks on hygiene and kindred subjects were much appreciated. Dr. Boileau had a good memory for detail, having travelled widely and read much. She had for every occasion an apt quotation, an appropriate illustration, or an amusing anecdote. She had a great gift for friendship and her loss will be deeply felt by a large circle of friends, people of many different classes and kinds.

THE LATE MR. H. D. FARNELL, F.R.C.S., O.B.E., J.P.

WE published last week a brief obituary notice of Mr. Henry Dawson Farnell. Since then we have received the following appreciations. The first, from Dr. A. Craigmile, is as follows: "Henry Dawson Farnell and I first met in the summer of 1875 at the Northern Hospital, Liverpool (now the David Lewis Northern Hospital), to which he came as senior house surgeon, and I as house physician; and so began a friendship which lasted without a break till now. Farnell had come straight from University College Hospital, where he had been under the influence of Marcus Beck—one of the junior staff. This young surgeon, shaking off the traditions of the London School, was struck by the reports of Lister's new antiseptic surgery, and had gone to Scotland to study under Lister himself. He returned full of enthusiasm for the new method, and so Farnell, inspired by Beck, with the sanction of his staff, introduced it to the Northern, and we were soon in the full swing of all Lister's ritual, as it then existed. Presently a marked change took place in the wards: suppuration disappeared, compound fractures healed kindly, and septicæmia and pyæmia were known no more, and so Farnell had the great honour of first introducing antiseptic surgery and Lister's methods to Liverpool.

The late Mr. Chauncy Puzey—one of our honorary surgeons—in his presidential address to the Liverpool Medical Institution many years after, paid a generous tribute to the work Farnell had done in this direction. Of his work in Eastbourne it is the province of others to speak. From the beginning we were drawn to one another by mutual tastes in many things, especially in literature and politics. He was a great admirer of Sir Walter Scott, and on holidays, spent together, he used to quote favourite passages and pithy sayings from his favourite novels, citing one incident after another. All who knew him well were aware of the interest he took in motoring to new places, where an old church with famous monuments and brasses and piscinæ was sure to claim his rapt attention, for he took the keenest pleasure in the history of his country and its old traditions, and knew nearly every cathedral well. He was ' the dearest friend and most unwearied spirit in doing courtesies '—ever loyal and unselfish and true to his principles wherever they might lead him."

Another colleague writes: "Farnell was not only a great surgeon, but a man to be trusted implicitly. His patients loved him for his tender care and unselfish devotion. In the prime of his life Farnell was a very type of mental and bodily vigour, and his energy was almost incredible. Even in the last months, when a certain failure of health necessitated some slacking off of labour, he stuck to such work as was possible ; on the very day of the seizure, which was to prove fatal in so short a time, he took his seat on the Bench—he had been a justice of the peace for nearly 20 years—and the first symptom of his illness occurred when he was parting from a patient. He thus died as he himself would have wished, 'in harness,' and has left a void in the profession which will indeed be hard to fill."

The Services.

CHANGES IN THE DIRECTORSHIP OF THE MEDICAL SERVICES.

IN July last Sir William B. Leishman took over from Sir John Goodwin the appointment of Director-General, A.M.S., resigning the Directorship of Pathology, in which he is succeeded by Colonel D. Harvey, while Major A. G. Rolleston is appointed Deputy Assistant-Director. On Oct. 1st Rear-Admiral Joseph Chambers will succeed Surgeon Vice-Admiral Sir Robert Hill as Director-General of the Medical Department of the Royal Navy. In the Indian Medical Service, as we announced on August 4th, Colonel Charles Harford Bowle-Evans became Director-General of Medical Services in place of Lieut.-General Sir C. H. Burtchaell, this being the first time that an officer of the I.M.S. has been appointed to be Director-General of Medical Services. At the same time the retirement of the Director-General, I.M.S., Sir William Rice Edwards, was announced ; he has been appointed representative of the Government of India on the Permanent Committee of the International Bureau of Public Health. This latter appointment was held by Major-General Sir Richard Havelock Charles, who has vacated office as president of the India Office Medical Board and medical adviser to the Secretary of State in Council, Major-General J. B. Smith taking his place.

ROYAL ARMY MEDICAL CORPS.

Capt. P. Carney retires, receiving a gratuity, and is granted the rank of Maj.

The undermentioned temp. Capts. relinquish their commns. and retain the rank of Capt. : A. St. J. Bateman, E. B. Jones, E. H. Milson, and M. Shipsey.

ARMY DENTAL CORPS.

Capt. R. W. Shortreed, late Spec. List, to be Capt.

RESERVE OF OFFICERS.

Lt.-Col. St. J. B. Killery having attained the age limit of liability to recall ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Capt. W. F. Denning (late 4th Bn., Duke of Wellington's Regt.) to be Major.

TERRITORIAL ARMY RESERVE.

The undermentioned officers having attained the age limit are retired and retain their rank : Lt.-Cols. A. L. Jones and W. McG. Young (with permission to wear the prescribed uniforms) ; Maj. W. T. Blackledge (with permission to wear the prescribed uniform) ; and Capt. W. J. C. B. Pitt.

The undermentioned relinquish their commns. and retain their rank : Capts. S. Sharples and W. Boyd ; Lts. A. L. Bastable and J. C. Jefferson.

Capt. F. D. Marsh, from General List, to be Maj.

General Hospitals : Lt.-Col. G. S. A. Ranking, having attained the age limit, is retd. and retains the rank of Lt.-Col.

INDIAN MEDICAL SERVICE.

Capts. R. H. Candy, Jamasji Cursetji Bharucha, H. Hingston, F. J. Anderson, and E. V. Morrison to be Majs.

ROYAL AIR FORCE.

Flight Lt. J. Paxton relinquishes his temporary commission on ceasing to be employed.

DEATHS IN THE SERVICES.

Surgeon-Captain Edward O'Malley, R.N., who died at Haslar Hospital on Sept. 20th, aged 51, was the son of the late Deputy Inspector-General O'Malley, R.N., and received his first commission in 1897. He saw service in the *Dido* during the Boxer rising, and was with the *Porpoise* in the Somaliland campaign. He served afloat with various ships of the Fleet during the Great War, and was only invalided out of the Navy 12 months ago. He leaves a widow but no children.

Medical News.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Post-graduate courses in various specialties will be given during October in London. Beginning on Monday, Oct. 1st, there will be a course on urology at St. Peter's Hospital for Stone. Demonstrations will be given in the out-patient department every afternoon, and in addition lecture-demonstrations by members of the staff, at 2 P.M., four times a week. A course of eight lectures on the more important diseases of tropical countries will be given by Dr. Low and Dr. P. Manson-Bahr at the London School of Tropical Medicine, beginning on Tuesday, Oct. 2nd. A course in laryngology, rhinology, and otology will be given at the Central London Throat, Nose, and Ear Hospital from Oct. 8th to 26th ; clinical lectures and demonstrations will be given by members of the staff each day from 9.30 to 5 P.M. A course on children's diseases will be given at the Victoria Hospital for Children from Oct. 8th to Nov. 3rd, and special clinical instruction in ophthalmology will be available at the Royal London Ophthalmic Hospital during the whole of the month. From Oct. 15th to 27th short intensive courses in cardiology and proctology will be given at the National Hospital for Diseases of the Heart and St. Mark's Hospital respectively. A short course in dermatology will also be held at the Hospital for Diseases of the Skin, Blackfriars, from Oct. 29th to Nov. 10th, and a fortnight's " refresher " course in general medicine and surgery from Nov. 5th to 17th. Copies of the syllabus and full particulars regarding the above courses can be obtained from the secretary to the Fellowship of Medicine at 1, Wimpole-street, London, W., and as in some cases the numbers are limited, early application should be made.

GUY'S HOSPITAL BIENNIAL DINNER.—This dinner will be held at the Connaught Rooms, Great Queen-street, London, W.C., on Wednesday, Oct. 17th, at 7 P.M., Mr. G. Bellingham Smith presiding. The hon. secretary is Mr. Arthur W. Ormond, from whom further information may be obtained.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL.—The winter session will commence on Thursday, Oct. 4th, at 4 P.M., when Mr. William Stuart-Low will deliver an address on the Rôle of the Mucous Membrane in Diseases of the Nose, Throat, and Ear.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, QUEEN-SQUARE, BLOOMSBURY, W.C.—The syllabus of the post-graduate course to be held from Oct. 8th to Nov. 30th has now been issued. The course will consist of lectures and demonstrations on the Pathology of the Nervous System on Mondays at 12 noon ; out-patient clinics on Mondays, Tuesdays, Thursdays, Fridays, 2 P.M. to 3.30 P.M. ; clinical lectures and demonstrations on the same days at 3.30 P.M. Dr. J. Godwin Greenfield will give a course of lectures and demonstrations on Neuro-Pathology on Mondays at 12 noon.

Medical Defence Union.—The annual general meeting of the Medical Defence Union will be held at the Royal Hotel, College Green, Bristol, to-day, Saturday, Sept. 29th, at 5 P.M., Sir Charles Ballance presiding.

Dr. Adam Patrick, of Glasgow, has been appointed Professor of Medicine at St. Andrews University in succession to Prof. A. M. Stalker.

St. Thomas's Hospital.—The old students' dinner will take place at the Princes' Restaurant, Piccadilly, on Oct. 26th, at 7 o'clock for 7.30. The chair will be taken by Mr. W. H. Battle.

Medico-Legal Society.—A meeting will be held at 11, Chandos-street, Cavendish-square, London, W., on Oct. 16th, when a paper will be read by Mr. W. Greaves-Lord, K.C., entitled Miner's Nystagmus, which will be followed by a discussion.

Medical Sickness, Annuity, and Life Assurance Society.—The annual general meeting of the company will be held at Lincoln House, 300, High Holborn, W.C. 1, on Oct. 1st, at 4 P.M. Among other business a proposal will be considered that the sum of £1 1*s.* should be paid to the chairman and each director for every attendance at the meetings of the board or of committees of the board and general meetings.

Pharmaceutical Society of Great Britain.—The opening of the eighty-second session of the school of pharmacy, 17, Bloomsbury-square, London, W.C., will take place on Oct. 3rd, when Dr. W. E. Dixon, F.R.S., will give the inaugural address at 3 P.M.

National Institute for the Blind.—The second "Sunshine House" for blind babies has been opened at Birkdale, Southport. Nearly five years ago the first home of the sort was established at Chorley Wood, Herts. Since then the home has always been full, while there has always been a long waiting-list of infants. The establishment and maintenance of these homes go far to relieve present misery and distress and to minimise the possibility of future hardships by creating the ability to overcome them.

Charing Cross Hospital Medical School.—The annual distribution of prizes will be held in the out-patients' hall of the hospital (entrance in King William-street) on Oct. 3rd, at 3.30 P.M. Dr. William Hunter will distribute the prizes and deliver an address entitled Some Problems of Modern Medical Education.

The *Annual Dinner of Past and Present Students* will take place on the evening of the same day in the Adelaide Gallery, Gatti's Restaurant, Strand, W.C., at 7 for 7.30 P.M., Dr. T. Watts Eden presiding. The guests present will include Lord Fairfax, Sir Donald Maclean, Sir Humphry Rolleston, and Prof. W. W. Chipman, of Montreal.

Psychological and Physical Development of the Child.—A series of six lectures for mothers on this subject will be held at Carnegie House, 117, Piccadilly. The lectures will be under the headings of the Baby (from birth to 5 years), the Child, and the Adolescent. The psychological aspect of infant life, childhood, and adolescence will be dealt with by Dr. H. C. Cameron on Nov. 6th, Dr. Niall on Nov. 13th, and Dr. Elizabeth Sloan Chesser on Nov. 20th; while the physical aspect will be discussed by Dr. Charles Anderson on Nov. 27th, Dr. Flora Shepherd on Dec. 4th, and Sir Bruce Bruce Porter on Dec. 11th. An introductory lecture by Dr. Crichton-Miller entitled the Well-meaning Mother on Oct. 30th, and a concluding one on Dec. 16th by Miss Smeeton, the Nurse and the Nursery, will complete the series. The lectures take place on Tuesdays at 3.15 P.M. Tickets (10*s.* 6*d.* for each lecture or £2 5*s.* for the series) may be obtained from Viscountess Erleigh, 65, Rutland-gate, London.

Donations and Bequests.—Mr. James Philip Bauer, of Manchester and Blackpool, left £1000 to the Manchester Royal Infirmary to endow a bed to be called the "James Bauer" bed; £100 each to St. Mary's and Southern Hospital, Ancoats Hospital, and many other bequests to Jewish charities in Manchester.—During the past month subscriptions and donations have been received by the Manchester Children's Hospital, totalling £1718, including donations from the Hospital Saturday Fund of £1388 and Salford Musical Festival of £95.—Local charities in Manchester have profited to the extent of £1613 from the result of the St. Leger Sweepstake in Rusholme: Manchester Royal Infirmary, £500; St. Mary's Hospitals, £400; Ancoats Hospital, £163; Rusholme Nurses Fund, £100; and some other institutions in proportion.

Cromer Cottage Hospital.—This well-equipped institution was presented to Cromer by the late Mr. G. W. Collison, and was opened on June 23rd, 1888. The hospital is a two-storied building, containing on each landing two large wards with eight beds in each, and two smaller wards for serious or operation cases, with two beds in each, the men's wards being on the ground floor, with an outside shelter for tuberculous cases, and the women's wards above, with a verandah opening out from the larger ward. The operating theatre is on the upper floor—a spacious apartment, about 21 feet by 20, with two large windows. For night operations an electric lamp is used and a new lamp is about to be installed at a cost of £50. The walls of the theatre are lined with glazed tiles, rounded off at all corners. A lift is installed. The hospital is provided with an X ray room, fitted up in June, 1913, by subscriptions from patients and well-wishers of Dr. H. C. Dent, on his retirement after 25 years' service. The resident staff consists of a matron, ward sister, and four probationer nurses. The medical staff is composed of the local medical men, Drs. R. Colvin-Smith, A. Burton and R. Grant, with two dental surgeons and a radiographer. Dr. F. W. Burton-Fanning, Norwich, is honorary consulting physician; Sir Hamilton Ballance and Mr. J. Burfield, of Norwich, honorary consulting surgeons, and Dr. A. J. Cleveland, Norwich, honorary consulting radiographer. The institution is supported by voluntary contributions, and fees are charged to patients as follows: Uninsured men and women, 10*s.* a week; insured men, 15*s.*, and insured women 12*s.* 6*d.* a week. Private patients are occasionally admitted at 3 guineas a week. The financial report for the year ending September, 1922, shows a balance of £153 4*s.* 10*d.* The medical report states that 262 patients were admitted during the year, 116 males and 146 females. Of these 245 were surgical cases, including 36 accidents, and 17 medical cases. Two hundred and six patients were discharged cured, 26 improved, and there were 17 deaths, and 11 patients remaining in the hospital. There were 95 X ray patients, hospital and private. There were 179 operations, including dental cases, and six operations under local anæsthesia. The daily average number of patients was 11, the average expenditure per patient £6 4*s.* 10*d.*, and the average expenditure per bed (20 beds) £81 15*s.* 5*d.*

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Oct. 2nd.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Presidential Address:
Mr. R. C. Elmslie: Manipulative Surgery.
Cases: The following cases will be shown by:—
Mr. Elmslie: Deformity of Spine of Tibia.
Mr. Laming Evans: The Result of Combined Steindler and Whitman Operations for Talipes Calcaneo-cavus.
Mr. W. H. Ogilvie: Three cases of Primary Myositis.
Mr. P. Bernard Roth: Fracture Dislocation of Radius.
Mr. Maynard Heath: Recurrent Dislocation of Inner End of Clavicle.
Mr. Whitchurch Howell: (1) Tendon Transplant for Wrist-drop; (2) Tendon Fixation for Foot-drop.

Thursday, Oct. 4th.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.
Specimens:
Mr. Alfred B. Danby: A Uterus removed for Concealed Accidental Hæmorrhage. (Cæsarean hysterectomy.)
Mr. Everard Williams: Adenomyoma in a Malformed Uterus.
Short Communications:
Dr. H. Williamson and Dr. G. F. Abercrombie: A case of Inversion of the Uterus caused by a Squamous-celled Carcinoma of the Fundus.
Mr. W. Gilliatt: Placenta Prævia in Three Successive Pregnancies.
Paper:
Mr. Gordon Luker: Treatment of Puerperal Septicæmia. (A new method.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Monday, Oct. 1st.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2.30 P.M., Dr. Saunders: Medical Wards.
Tuesday.—11 A.M., Dr. Paterson: Medical Wards. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.

Wednesday.—10 a.m., Dr. Saunders: Medical Diseases of Children. 12.15 p.m., Dr. Burnford: Medical Pathology. 2 p.m., Dr. Pernet: Skin Dept.

Thursday.—10 a.m., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 p.m., Mr. Bishop Harman: Eye Dept.

Friday.—10 a.m., Mr. Dudley Buxton: Dental Dept. 12 noon, Dr. Endean: Venereal Diseases. 2 p.m., Mr. Sinclair: Surgical Out-patients.

Saturday.—9.30 a.m., Dr. Burnford: Bacterial Therapy. 10 a.m., Dr. Saunders: Medical Diseases of Children. 10 a.m., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 a.m. to 6 p.m., Saturday, 10 a.m. to 1 p.m., In-patients, Out-patients, Operations, Special Departments.

ST. MARY'S HOSPITAL MEDICAL SCHOOL POST-GRADUATE COURSE.

Monday, Oct. 1st.—11 a.m., Mr. Aleck Bourne: Anticipation of Mechanical Difficulties in Labour, illustrated by lantern slides. 12 noon, Dr. Wilfred Harris: Encephalitis Lethargica. 2 p.m., Dr. Graham Little: Diagnosis of Some Common Diseases of the Skin, illustrated by cases. 3 p.m., Prof. F. Langmead: Some Functional Disorders in Young Children.

LIVERPOOL UNIVERSITY CLINICAL SCHOOL.

(At 3.30 p.m. each day.)

Monday, Oct. 1st.—(At the Children's Hospital.) Dr. Fordyce: Glycosuria: (1) Cases of Diabetes Mellitus under Treatment with Insulin; (2) Cases of Non-diabetic Glycosuria, Diagnosis, Tests, Treatment.

Tuesday.—(At the Southern Hospital.) Mr. Douglas-Crawford: Common Surgical Lesions of the Jaw.

Wednesday.—(At the Northern Hospital.) Dr. Bligh: Types of Mental Defects in Children.

Thursday.—(At the Stanley Hospital.) Dr. Gullan: Diseases of the Endocrine Organs—notably Thyroid Gland, Pancreas, and Suprarenal Gland.

Friday.—(At the Royal Infirmary.) Dr. Abram: Clinical Medicine.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

Tuesday, Oct. 2nd.—4.15 p.m., Dr. F. E. Tylecote: Some Recent Abdominal Cases.

Friday.—4.15 p.m., Dr. Judson S. Bury: The Regional Diagnosis of Paralysis.

Appointments.

Ash, W. M., M.B., B.S. Lond., D.P.H., has been appointed Deputy Medical Officer of Health for the County of Middlesex.

Berry, R. B., M.D., Ch.B. Vict., D.P.H., Medical Officer of Health for Gloucester.

Rowan, J., M.B., C.M. Glasg., an additional Ophthalmic Specialist Medical Referee under the Workmen's Compensation Act for the Sheriffdom of Lanark.

Stansfield, Tom, M.B., B.S. Lond., Hon. Assistant Physician to the Royal Berkshire Hospital, Reading.

Turner, Mary I., M.B., Ch.B. Vict., D.P.H., Assistant M.O.H., Chester.

Certifying Surgeons under the Factory and Workshop Acts: **Lees, J. A.**, M.B., Ch.B. Vict. (Rawtenstall); **Bartlett, J. H.**, L.R.C.P. Edin., L.R.F.P.S. Glasg. (Harrold District of Bedford); **Carson, C. O.**, L.R.C.P. Lond., M.R.C.S. (Lydney).

Vacancies.

For further information refer to the advertisement columns.

Bristol Royal Infirmary.—Hon. Dental Surgeon.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Three Registrars.

Croydon Borough Sanatorium, North Cheam.—Res. Med. Supt.

Croydon General Hospital.—Jun. H.S. £150.

Derbyshire Royal Infirmary, Derby.—Two H.S.'s., H.P., &c. Each £200.

Duff House Private Hospital, Ruthin Castle, North Wales.—Res. Asst. P. £300.

Egyptian Government School of Medicine.—Lecturer in Experimental Physiology. L.E.540 a year.

Guildford, Royal Surrey County Hospital.—H.S. £150.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. Also Res. M.O. £500.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and Asst. Cas. O. £50. H.S. £50.

Hull City Asylum.—Jun. Asst. M.O. £300.

Italian Hospital, Queen-square, W.C.—Asst. Anæsth.

King's College Hospital.—Clin. Assts. Med. and Surg. Out-patient Officers. Sambrooke Med., Surg., and Obstet. Reg.

Kingston-upon-Hull City and County.—R.M.O. £400.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

London Lock Hospital, 91, Dean-street, W.—H.S. £200.

Middlesex Hospital, W.—Radium Officer. £300.

Mount Vernon Hospital for Diseases of the Chest, Northwood, Middlesex.—Asst. Phys.

Newcastle-upon-Tyne City Hospital for Infectious Diseases.—Res. Med. Asst. £350.

Norwich, Norfolk and Norwich Hospital.—Hon. S.

Oswestry, Shropshire Orthopædic Hospital.—Res. Surg. O. £500. Two H.S.'s. £250.

Paddington Green Children's Hospital, W.—H.P. and H.S. Each £150.

Prince of Wales's General Hospital, Tottenham, N.—H.S. £150. H.P. £150. Also Jun. H.S. and Jun. H.P. £110 each.

Royal Eye Hospital, St. George's Circus, Southwark, S.E.—Hon. Asst. S. Also Jun. H.S. £75.

Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.

St. Pancras Metropolitan Borough.—M.O.H. £1100.

South London Hospital for Women, Clapham Common, S.W.—Temp. Asst. P.

South Mimms, Barnet. Clare Hall Hospital and Sanatorium.—Asst. M.O. £350.

Staffordshire General Infirmary, Stafford.—H.P. £150.

West Bromwich and District Hospital.—Res. Asst. H.S. £180.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. H.S.'s. £150 and £100 respectively.

York, North Riding Mental Hospital.—Temp. Asst. M.O. 7 guineas weekly.

The Chief Inspector of Factories, Home Office, London, S.W., announces a vacant appointment at Wirksworth, Derbyshire.

Births, Marriages, and Deaths.

BIRTHS.

Brewerton.—On Sept. 23rd, at Harley-street, W., the wife of Elmore Brewerton, F.R.C.S., of a daughter.

Gilmour.—On Sept. 17th, at Dora-road, Wimbledon Park, S.W., the wife of Dr. A. Gilmour, of a son.

Macrae.—On Sept. 20th, at Edwardes-square, Kensington, the wife of Captain A. Campbell Macrae, I.M.S., of a daughter.

Neighbour.—On Sept. 19th, the wife of Dr. Philip Neighbour, of Feltwell, Norfolk, of a daughter.

MARRIAGES.

Banfield—Osborn.—On Sept. 20th, at St. Mary's the Virgin, Dover, by the Revd. Canon Elnor, Capt. E. L. Banfield, *M.C.*, Royal Irish Fusiliers Reserve of Officers, eldest son of Mr. R. Banfield, O.B.E., Deputy Chief Constable of Cornwall, and Mrs. Banfield, of Bodmin, to Hylda Gwynedd (Nancy), second daughter of Dr. F. A. and Mrs. Osborn, of Clyde House, Dover.

Firman-Edwards—Anderson.—On Sept. 15th, at St. John's Church, Coulsdon, Surrey, Langdon Firman-Edwards, M.B. Cantab., to Hylda, younger daughter of Mr. and Mrs. C. Labat Anderson, The Durdans, Purley, Surrey.

DEATHS.

Boileau.—On Sept. 17th, Margaret Lucy Augusta Boileau, M.B., B.S., daughter of the late Sir Francis Boileau, Bart., of Ketteringham Park, Norfolk, aged 56 years.

Maguire.—On Sept. 20th, at Stony Stratford, Bucks, Thomas S. Maguire, M.D., J.P., aged 78.

O'Malley.—On Sept. 20th, suddenly, at Haslar Hospital, Surgeon-Captain Edward O'Malley, R.N. (retired), of St. Ronans-road, Southsea.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE POSITION OF THE FRIENDLY SOCIETIES.

THE following is an abstract from the presidential address delivered by Mr. T. W. Huntley (Newcastle-upon-Tyne) at the National Conference of Friendly Societies held at Aberystwyth on Sept. 20th–22nd.

The question of the moment, said Mr. Huntley, was the new contract to be made with the doctors. The pre-war fee was 7*s.* 3*d.* per insured person per annum. After a demand from the doctors an arbitration award given early in 1920 raised the fee to 11*s.*, the difference being provided by an Exchequer grant and not by Health Insurance funds. A reduction of the fee to 9*s.* 6*d.*, effected in 1922, was to continue till Dec. 31st. After the issue of the Geddes Report on national expenditure, the Cabinet accepted a recommendation for the abolition of the Exchequer grant for medical service, and decided to introduce a bill to raise the contributions of the insured persons and employers. The proposal was strenuously opposed by the Consultative Council, on the ground that the time was inopportune for raising contributions, and the Council made a suggestion, which was accepted, that the amount required to maintain the contract with the doctors from April 1st, 1922, to Dec. 31st, 1923, should be borne by the accumulated funds of the approved societies.

Three points emerged from this position: (1) The possibility of a return to the pre-war per capitation fee of 7*s.* 3*d.* was clearly contemplated; (2) more than 7*s.* 3*d.* could not under any circumstances be paid from insurance funds without the full knowledge and approval of approved societies; (3) no repudiation by the Ministry of this condition had been made, but on the contrary Sir Alfred Mond, the then Minister, agreed to consult the approved societies.

Position of the Doctors.

The doctors' contentions, Mr. Huntley went on to say, were as follows: 1. The reduction of the capitation fee from 11*s.* to 9*s.* 6*d.* was agreed to on patriotic grounds and in ignorance of the fact that the insurance funds would bear the charge. 2. There were no grounds for a reduction of the present fee of 9*s.* 6*d.*, but there were reasons for an increase to 10*s.* 4*d.* and more. 3. The insurance funds were accumulating by millions a year and could carry a higher medical fee, and the fee should be a first charge upon the funds.

Criticism of Doctors' View.

In criticism of these contentions Mr. Huntley said that seeing that the additional payment was to be met by Exchequer grant they were not a party to the award of 11*s.*, but its grant caused them some surprise, and the Minister of the day said it was too high. To say that there was no ground for a reduction now was to ignore the fall in the cost of living since early in 1920, but many thousands of other people had not been allowed to ignore it. Nor could the following facts be overlooked: (1) That the original fee of 7*s.* 3*d.* was greatly in excess of what was received for club practice in pre-insurance days; (2) that no attempt had been made by reference to number of attendances per insured person or other statistics to prove that the fee is not a fair remuneration for the services rendered; (3) that the 7*s.* 3*d.* capitation fee gave an augmentation to the income of a large number of the profession such as no other circumstance has ever done and raised permanently their standard of living—that, in short, the doctors had done exceedingly well out of health insurance.

The claim that because the insurance funds were growing the present per capita fee, or a higher one, could be paid, and that this should be first charge on the funds, could not be admitted by any student of insurance. It meant the Act for the doctors, not the doctors for the Act. Of course the funds were growing, but with reference to the surpluses declared at the last valuation they could not overlook the actuary's warning that these had arisen through circumstances which could not be expected to be repeated—the abnormal death-rate of members of military age and the consequent premature release of reserves and high rates of interest.

Negotiation or Resistance.

It was their great desire to live and work in amity with the members of the medical profession. Theirs was a noble calling, and it was right to say that in the main panel doctors had given good service under their contracts. The Friendly Societies were not out for an underpaid medical service, but they did not think the original payment was less than the value of the service rendered. If the doctors could secure more from other sources they would assume the same attitude of non-intervention as before. The situation was not one for dictation by doctors and the societies must not falter in defending their members. They were prepared to negotiate, but if it was proposed to distribute beyond the present statutory limits any part of the funds for which they were trustees, without their full knowledge and agreement, then they would offer the most determined resistance.

A Resolution.

The Conference later passed a resolution to the effect that the sum paid from the funds of approved societies to insurance panel practitioners at the period when the agreement was terminated by the Government, on the recommendation of the Geddes Committee, was ample for the services rendered, and that no increase beyond 7*s.* 3*d.* per insured person payable out of approved societies' funds could be agreed upon without the consent of the societies.

A MATERNITY NURSING HOME ON HOSPITAL LINES.

MEDICAL men are often asked to name suitable homes to expectant mothers of the middle classes who wish to be confined away from their homes. The privilege of residing in the same house as her accoucheur has hitherto been largely confined to the class of women who use the big maternity and lying-in hospitals. Our attention has been drawn to Stone Field, Kidbrook-grove, Blackheath, London, S.E. 3, which is a large private house adapted as a maternity nursing home with two resident obstetricians and a staff of nurses holding the C.M.B. certificate. The home has 20 beds arranged in private rooms (7 to 11 guineas a week) and cubicles (6 guineas a week), these charges including motor service, patients being fetched free of charge from London and neighbouring districts, the service working day or night as required. Medical accouchement outfit is also provided free. With regard to medical fees, patients make arrangements with one of the residents or with their own doctor, who may conduct the confinement if it is desired. The house has spacious rooms and an attractive garden. Further particulars can be obtained from the matron of the home.

PUBLIC HEALTH IN BIHAR AND ORISSA.

(Concluded from p. 636.)

The Effect of Improved Agricultural Conditions on Crime.

IN the jails [1] of this province there was a considerable decrease in the numbers confined, from a total of 51,272 in 1920 to 42,290 in 1921, the average daily population being 5990, against 7845 in the previous year. The decrease is attributed by Colonel Sir H. E. Banatvala, C.S.I., I.M.S. (retired), Officiating Inspector General, to improved agricultural conditions, as shown by the large decrease (2423) in the offences against property; and in convictions for dacoity, which had been 361 in 1919 and 179 in 1920, but were only 111 in the year under report. The majority of the convicts were Hindus, but in proportion to the numbers of the free population in the province Mohammedans contributed 0·408 per 1000, Hindus 0·298, and Christians 0·227 per 1000. Of the total, 91·17 were illiterate. There was a considerable decrease in the number of youthful or juvenile offenders (under 20 years of age), from 855 in 1920 to 644 in 1921. Sir H. Banatvala remarks, very truly, that "it is unfortunate that we were obliged to keep in our juvenile jail boys under 16, lads of 16, and adolescents up to 21 years of age—all mixed together." He points out that 58 juveniles (under 16) were sentenced to from 2 to 15 days imprisonment, mostly for offences against property. "What useful purpose can be served by sending boys to a jail for such short periods I cannot imagine, and I think magistrates would exercise a sound discretion by availing themselves of Section 562, Criminal Procedure Code, or by releasing them after whipping—i.e., where allowed by law." It is to be hoped that this opinion will receive the attention it deserves. There is no doubt that juvenile offenders may receive very great and lasting benefit when undergoing terms of imprisonment long enough for the good influences brought to bear upon them to produce their effect; but time is required.

With regard to the health of the prisoners, the ratios of admission to hospital and average daily sick were 1163·0 and 48·9 per 1000, as compared with 885·6 and 42·1 in 1920. The death-rate also increased from 27·0 to 31·0, but this was below the mortality for the province (32·8). Gaya jail had the highest death-rate (74·1), a considerable increase over that of the previous year (55·9), due to cholera (11 deaths) and tubercle (13). At Cuttack the mortality was 50·2, compared with 14·6 in 1920, due chiefly to dysentery. There was an increase in cholera (32 cases and 14 deaths, against 13 and 5 in 1920); 23 cases occurred at Gaya (11 fatal). On the other hand, dysentery, so generally a scourge in jails, though causing 850 admissions to hospital, was fatal in only 24 cases (against 858 and 52 in 1920).

---

[1] Patna Government Press, 1922.

In many instances the predisposing cause is hookworm infection, with which parasite "the average percentage of infection in this province is about 70." Malaria caused 1302 admissions to hospital, but only 3 deaths (255·4 and 0·5 per 1000). For pulmonary tuberculosis there were 87 admissions and 35 deaths. Of the whole number of 14,284 convicts discharged during the year from the Central and Districts jails, 60 per cent. gained and only 16 per cent. lost weight, a most satisfactory result from the public health point of view.

Report on Vaccination.

The Report on Vaccination [2] for 1921–22, by Lieut.-Colonel W. C. Ross, states that the total number of operations performed fell from 1,060,485 in the previous year to 939,851 during the period now reviewed (April, 1921, to March, 1922). The decrease is attributed to political unrest and active interference with the work of the staff: "the vaccinators are now unwilling to work in many places, and their numbers are likely to decrease, as they cannot realise their fees fully." Of the total operations (925,134) performed by the staff, 98·26 per cent. were successful. The small-pox mortality in the province during the last five years has amounted to 55,691, while in the preceding quinquennium it had been 40,437. Colonel Ross considers that the disease cannot be "effectively dealt with and stamped out unless vaccination is made compulsory throughout the province"; he would recommend that the age should be extended to one year, that vaccination should be free, and that the supervision should be delegated to district boards and municipalities.

Hospitals and Dispensaries.

During the year 1921 25 hospitals and dispensaries [2] were opened in Bihar and Orissa, and five were closed, the total number of these institutions at the end of the year being 454; moreover eight new dispensaries have been added during 1922. This progress is encouraging and satisfactory. The report states that "it is hoped to carry through the ideal scheme of having a dispensary for each *thana* [police station] or for an area of each five square miles, in which area the medical officer of the dispensary will be responsible for the sickness of his area." As the area of the province is 83,181 square miles, this would mean 16,636 hospitals or dispensaries; probably "for each five miles square" is intended, which would mean 3327 institutions. "The great point is to have a medical officer who can reach at once the spot where epidemic disease breaks out, and so deal with it in the earlier stages, when it is possible to take effective action." This is undoubtedly a true economy in every way; *obsta principiis.* It is unfortunate that there is difficulty in getting doctors of the sub-assistant surgeon class, who at present prefer to avoid Government service; the cadre is always under strength. Altogether 4,003,991 patients were treated in 1921 at the various hospitals and dispensaries in the province, of which total 67,850 were in-patients; in 1920 the corresponding numbers had been 3,851,953 and 67,095. In the "State-Public, Local Fund, and Private-Aided Hospitals and Dispensaries" the total number treated was 2,962,623; the daily average of in-patients being 1781 and of out-patients 17,873. There was an increase in cholera mortality in the general population from 0·7 (in 1920) to 2·6 per 1000; the dispensary attendance rose from 4487 (with 605 deaths) to 12,230 (and 622 deaths) in 1921. "Until the rudiments of sanitation are thoroughly appreciated by the people, so long will the water-supplies of small towns and villages become infected on the return of villagers from cholera-infected parts. . . . All these matters require special consideration in the establishment of a public health organisation, which is urgently needed for the prevention of epidemic disease." As to plague, of which 1657 cases were treated, against 2161 in the previous year, "there is little that can be done with conditions as they are in Indian towns and villages." The people understand and appreciate the evacuation of houses, but what is required are rat-proof houses and grain-stores, and anti-plague vaccination. Small-pox admissions fell from 1532 in 1920 to 488 in 1921, but malaria increased from 755,423 to 824,252; owing to the increased cost of quinine it is impossible to obtain enough to allow it to be used in effective doses. There was some increase in pulmonary tubercle (6051 admissions and 143 deaths, compared with 5699 and 127 in 1920); intravenous injection of sodium morrhuate has given good results. There was also an increase in kala-azar (12,423 cases, against 8520 in 1920, and 5281 in 1919); treatment by intravenous injections of tartar emetic is much appreciated, and has no doubt led to an increase of admissions. In the eight leper asylums there were 1967 resident patients, compared with 1852 in 1920; this does not necessarily mean that leprosy is on the increase, but indicates that the lepers recognise the benefits of treatment. It is proposed to form a leper colony in the Santal Parganas (Bhagalpur Division), with the aid of the Santal Mission, to which a debt of gratitude will be due for this excellent scheme. A new radium institute has been built at Ranchi, and work in this direction has already been started by Lieut.-Colonel J. C. S. Vaughan, I.M.S. (retired), who is an expert in this treatment.

Progress is reported in many other directions, including improvement in maternity methods, the establishment of a medical college, and the introduction of post-graduate courses for assistant surgeons. Colonel Austen Smith, C.I.E., Inspector-General of Civil Hospitals, concludes his report by referring to the scheme for post-graduate courses for assistant and sub-assistant surgeons now in operation at the Calcutta Medical College, which will ensure their being kept up-to-date with medical science; and hopes that the pay and prospects of sub-assistant surgeons in the province will be improved, "as they are a very deserving body of Government servants, and I wish to see them a contented service."

THE TREATMENT OF WHOOPING-COUGH WITH ARTIFICIAL SUNLIGHT.

Dr. Ferdinand Schotten,[1] of Cassel, has succeeded in relieving the distressing condition of the paroxysmal cough followed by vomiting which makes the nursing of whooping-cough such a trial to parents. He reports 10 cases, all between the ages of 1 and 5 years, and all in the stage between the eighth and fourteenth days after the first attack of coughing, that is between the catarrhal and convulsive stages, the most distressing period for the mothers. The children all had marked mucous expectoration and frequent paroxysms. The children were submitted to artificial sunlight with the chest exposed for five minutes every two days, the exposure increasing by three to five minutes each time. All the cases reacted promptly, and after three to four treatments the attacks became less frequent, especially during the night, when the children were suddenly awakened by an irritation in the throat, had to sit up, and finished by vomiting. Dr. Schotten does not think that pertussis can be cured by this treatment, but by reducing the attacks of vomiting the child feels better, the appetite improves, nourishment can be maintained, and weight is not lost. It is recognised that after whooping-cough the glands in the hilum of the lung become swollen, and remain so for a long period, and that tuberculosis often supersedes the disease. Dr. Schotten suggests that by improving the general condition of the patient the swelling of the glands may be prevented from becoming chronic and from forming a medium for other infections.

THE SPAS OF WESTERN ENGLAND AND CENTRAL WALES.

The Great Western Railway Company have issued an attractive little booklet summarising the therapeutic advantages of the various spas and health resorts served by their lines [2] in the West of England and in Central Wales. In an introduction to the booklet the effect of the recent war upon the British spas is traced, and reference is made to the improved facilities for travel, hotel accommodation, and entertainment, which now enable these resorts to compete on equal terms with those of the Continent. Treatment at a British spa is now within reach of many people for whom visits to continental resorts are out of the question, and the comparative cheapness and ease of travel to the former are here emphasised. The spas dealt with are Bath, Cheltenham, Church Stretton, Droitwich, Leamington Spa, Malvern, Torquay, Weymouth, Builth Wells, Llangammarch Wells, Llandrindod Wells and Llanwrtyd Wells. Two or three pages of historical and geographical description, with notes of the type of cure practised, and in many cases with analyses of the waters, are included in regard to each of the places named; good illustrations and a summary of the specific therapeutic benefits obtainable enhance the value of this little publication.

COMBINED W.C. TRAP AND SOIL-PIPE BRANCH.

Messrs. John Knight and Sons, of 26, Cale-street, Chelsea, S.W. 3, have sent us particulars of a combined W.C. trap, and soil-pipe branch which is carried through the wall of the house. There are no joints to either drain or soil-pipe within the house, and as the trap is fixed clear of the floor the space beneath the pan can be easily kept clean. The pipe branches are made for 9 in., 14 in., and 18 in. walls.

VALENTINE'S PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS—Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Valentine's Meat-Juice

For **Quieting** the **Irritable Stomach** in **Pregnancy**, for **Rapidly Restoring** the **Vital Forces** in **Hemorrhage**, for **Sustaining** and **Strengthening** in **Long** and **Exhausting Labor, Valentine's Meat-Juice** is Extensively employed in

Obstetrical Practice

Dr. M. DeCristoforis, *Prof. Lecturer on Midwifery and Gynæcology, Milan, Italy:* "The preparation, VALENTINE'S MEAT-JUICE, has been successfully used by me in a serious case of acute puerperal hemorrhage. The patient could take no food or drink. VALENTINE'S MEAT-JUICE was completely retained and restored very promptly the strength and the cardiac impulsion."

Dr. E. Duloroy, *Physician Accoucheur to the International Hospital, Paris, France:* "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is today in good health."

For Sale by European and American Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY.
D 135 **RICHMOND, VIRGINIA, U. S. A.**

Griffith's
DISEASES OF
Infants and Children

Dr. Griffith has had long years of experience with a very large private and hospital practice. He gives you here a summary of that experience—a complete treatise on pediatrics, set down in definite form. The work is systematically arranged, taking up in separate chapters anatomy, physiology, hygiene, therapeutic procedures, diseases of the newborn, infectious diseases, general and nutritional diseases, respiratory lesions, circulatory derangements, genito-urinary diseases, nervous and mental diseases, conditions of the bones, hematology, diseases of the glands, dermatology, ophthalmology, and otology. Numerous case histories are given, and frequently the condition of the patient over a period of time is told and shown. The large number of temperature, pulse, blood-pressure, respiration, and other charts form a feature not usually found in other works on pediatrics.

"The most complete and up-to-date textbook on children's diseases in the English language, and one which may challenge comparison with any system of pædiatrics by English or foreign writers. The work . . . . is well printed on excellent paper and lavishly illustrated."—BRITISH JOURNAL OF CHILDREN'S DISEASES.

Diseases of Infants and Children. By J. P. CROZER GRIFFITH, M.D., Professor of Pediatrics in the University of Pennsylvania. Two octavo volumes totalling 1500 pages. Illustrated. **Cloth, 90s. net.**

McKenzie's Exercise in Education and Medicine *"is an excellent book. Large as the subject is, the whole ground is covered and the author has dealt with its varied aspects equally well. It is so well written that, copious as the volume is, and full of technical details, it is interesting to read from end to end, while it would form an admirable compendium for reference both to those engaged in education and for general practitioners of medicine.*—THE LANCET.

By R. TAIT McKENZIE, B.A., M.D., Professor of Physical Education, and Director of the Department, University of Pennsylvania. Octavo of 600 pages, with 445 Illustrations. **Cloth, 24s. net.**

Einhorn's Lectures on Dietetics: *"General principles rather than detailed regimes are dealt with, and on this the writer may be heartily congratulated, for it saves his book from the dogmatism which makes many larger volumes illogical and unreadable. Special chapters on duodenal and rectal feeding are of great practical value."*—THE LANCET.

By MAX EINHORN, M.D., Emeritus Professor of Medicine at the New York Post-Graduate Medical School. 12mo of 244 pages. **Cloth, 10s. 6d. net.**

Barker's Clinical Medicine: *"These lectures are an education in themselves, and also a pleasure to read, as they show considerable literary ability. A word of praise may be added for the excellence of the illustrations and for the many striking case records, which carry conviction as to the soundness of the author's methods."*—CLINICAL JOURNAL.

By LEWELLYS F. BARKER, M.D., LL.D., Emeritus Professor of Medicine, Johns Hopkins University. Octavo of 617 pages, illustrated. **Cloth, 35s. net.**

Mellish's The Writing of Medical Papers *"is intended to help untrained and partly trained writers to prepare for publication articles that will convey information with brevity, accuracy, and clearness. We may say that the intention has been quite successful; many writers, to say nothing of busy clinicians, will find useful information in this practical little work."*—THE LANCET.

By MAUD H. MELLISH, Editor of the Mayo Clinic Publications. 12mo of 157 pages. **Cloth, 7s. 6d. net.**

Out-patients are seen every afternoon of the week at 2 P.M. and every evening (except Saturday) at 6 P.M., when instruction is given by members of the Hospital Staff.

Special courses of instruction, including Pathological work in the Laboratory, can be arranged.

For further information, including fees, apply to M. G. HANNAY, M.D., M.R.C.P., Dean.

The "Safe" SAFETY PIN

The "M.D." is the most efficient Safety Pin ever designed for surgical bandages and nursing purposes. Curved in form and with a bayonet, or triangular point it passes readily through several folds of fabric, and by reason of its shape needs no special care in direction, the point naturally trending upward and outward.

Made of a silverite compound and absolutely non-rusting.

„ABEL MORRALL'S "M.D" SURGICAL SAFETY PIN

No Surgeon's equipment is complete without the handy, quickly adjusted "M.D." Safety Pin. Made in five sizes, 0, 1, 2, 3, 4.

Obtainable from all Surgical Supply Houses

Abel Morrall Ltd., Redditch

THE ONLY METAL LIMB WITH A GUARANTEE.

THESE limbs are at once the most comfortable, lightest, yet strongest limbs procurable. They are made of a metal known as Duralumin, which is as light as aluminium, but as strong as steel. The bucket is perforated all over to ensure coolness, greater resilience, and hence more comfort in wear. The heel is self-acting, and actually lifts the leg in use, thus giving a wonderfully natural action. We have received letters of keen appreciation from practically all whom we have fitted. This type of leg can be adapted for any amputation, and every one is fully guaranteed for two years.

We will gladly send a representative with a model to any surgeon, medical man, or anyone interested.

Send for particulars to the Inventors and only Makers,

A. E. McCLEAN & SONS,

Telephone : Gerrard 7664.

THE LONDON
MEDICAL EXHIBITION

Organised by the Management of the Exhibition of the 17th International Congress of Medicine, 1913, and the Fifth Clinical Congress of Surgeons, 1914.

THE CENTRAL HALL, Westminster, S.W.

Monday, Tuesday, Wednesday, Thursday, and Friday,

OCTOBER 1, 2, 3, 4, and 5, 1923,

From 12 noon till 6.30 p.m. daily.

THIS Exhibition, first established in 1905, and held in the Central Hall for the past four years, has proved, in view of the large number who visit it annually, to be greatly appreciated. Its scope has this year been very considerably enlarged, more accommodation has been provided, and the display of the latest in the medical, hygienic, dietetic, surgical, optical, and dental sections will be found of more than usual interest.

The attendance is strictly confined to the Profession, and the public are not admitted. Last year the Exhibition was visited by several thousand Doctors.

A handsome Reception Room, where catalogues and other literary matter relating to the Exhibition can be obtained, will be at the service of the Profession; also a spacious Tea Room in which light refreshments will be provided and where a well-known orchestra will perform each day.

Invitation cards will be sent to every member of the Profession residing within a 50 mile radius of the Hall. Those in the Provinces who do not receive cards, desiring to visit the Exhibition, can obtain same on application to THE SECRETARY, The London Medical Exhibition, 194–200, Bishopsgate, London, E.C., or at the Central Hall during the Exhibition week.

PRESS OPINIONS *of the* EXHIBITION.

The "Lancet" said:—

> "The London Medical Exhibition . . . . has matured by process of time into a most interesting display of the products of applied scientific work. Each succeeding year its claims have appealed more strongly to the members of the medical profession owing to the sincere and indefatigable efforts of its promoters to make it a real demonstration of surgical, medical and pharmaceutical advances. The reproach against it from some quarters that it is the mere fulfilment of a trade purpose may be dismissed in view of the close interest taken in the proceedings by the large number of professional men who attend. It seems evident that they go because they welcome the opportunity of making a near-at-hand inspection of what is being done to insure that medical accessories should contribute in the closest way to successful treatment. The exhibition affords, in fact, a very convenient channel for presenting to medical men, particularly in the metropolis, the interesting developments in pharmacy, medical, surgical and sanitary appliances, special dietetics, and so forth, which take place year by year."

"The Medical Press," October 11, 1922, said:—

> "With every succeeding year the evidence becomes more manifest that the annual London Medical Exhibition meets with increasing appreciation from the medical profession. That is not surprising, because the organisers of the Exhibition, being closely identified with the profession, are in the position to judge what is required for the purpose. Their enterprise is never lacking; their arrangements are always up to date and perfect; they aim at making the re-union of practitioners pleasant and, above all, profitable. With success has come the power to exercise an exclusiveness in respect of the exhibits, and by this means the standard of the Exhibition as a whole has been raised. *Hence there is nothing of the kind in this country able to compete with it in design, in popularity and in effectiveness.* So far as the exhibiting firms are concerned, the opportunity is valued as a special occasion for bringing under the direct notice of the profession the newest thing in pharmacy, in instruments, and in the allied branches of the trade which cater for medical requirements. The fact that this is so has now become recognised, and has much to do in accounting for the large attendances of consultants, specialists, and members of the profession generally which these exhibitions annually attract. The success attained this year was greater than on any previous occasion."

A Stylish Saloon

LUXURY at small cost. A saloon car you will be proud of in any company.

The New Jaeger Underwear

A Chest Specialist (Harley Street) writes:—

"In my opinion this invention of a Two-layer stockinet weave constitutes a distinct advance. The layers are so ingeniously woven that, for all practical purposes, the material behaves as a single fabric, whilst the air contained within the meshes acts as a bad conductor of heat, renders the garments more hygienic and, at the same time, lighter in weight than their somewhat bulky winter-weight predecessors.

In wear the fabric is warm and comfortable, and the texture is fine enough not to be irritating."

OFFORD
Established more than a Century
& SONS LTD

An Unique Scheme for the MEDICAL PROFESSION

WE have devised a plan which combines the advantages of owning and hiring a motor car, eliminating the drawbacks of both. Six ideals are secured as follows :—

1. Minimum capital outlay.
2. All payments out of income.
3. A new car every 1, 2 or 3 years.
4. Maximum efficiency and appearance.
5. Lowest maintenance costs.
6. An up-to-date car always.

THE following typical example illustrates the start and early progress of the scheme, on the basis of the supply of a new car each year. It clearly shows how the first deposit is the only capital expenditure ever paid, all further payments being arranged to suit the purchaser's income :—

EXAMPLE—

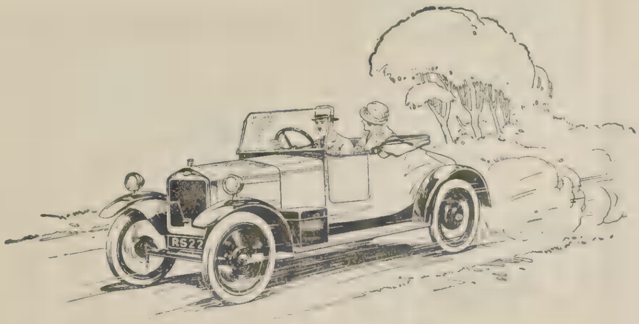
A NEW CAR EVERY YEAR.

	£	s.	d.
Cost of medium-priced vehicle	350	0	0
Interest for first year	17	10	0
Total	367	10	0
Cash payment on delivery	91	17	6
Balance	275	12	6
12 monthly instalments of £16	192	0	0
Balance	83	12	6
Possible cost of second car	325	0	0
	408	12	6
Estimated allowance for used car	175	0	0
Balance	233	12	6
Interest during second year	11	13	8
	245	6	2
12 monthly instalments of £16	192	0	0
Carried forward to next car	53	6	2

THE less often a new car is arranged for, the lower are the periodical payments in proportion. The scheme goes on indefinitely until you wish to stop it. Write for our leaflet on the subject or call at our Showrooms. All points can be made perfectly clear.

THE maximum efficiency and pleasure is to be got out of a car when it is new, and our scheme gives you a new car all the time.

AS in hiring, your commitments are a certain quantity, and the pleasure and convenience of owning is included. What better combination could be offered ?



94, Gloucester Road,
London, S.W.7

The Best the World produces

Wolsey for Health!

THE more widely Wolsey Underwear is adopted the less will be heard of colds and chills and of the many mischiefs that follow in their wake.

There is nothing yet invented or discovered to equal Wolsey's pure wool for keeping the body at just that right evenness of temperature on which good health depends.

Wolsey allows the skin to breathe, helps weak circulation, prevents overheating or too sudden cooling, absorbs perspiration without becoming cold or clammy.

Excellent for the sturdy, it is simply priceless for the delicate and those who must 'take care.'

There are Wolsey Pure Wool Undergarments and Hosiery for all and with every garment goes the famous Wolsey guarantee to replace free of cost if it should shrink. Wolsey is sold everywhere.

DESOUTTER BROS. LTD.

MAYFAIR 4332. 73, BAKER ST., LONDON, W. 1

THE RECOGNISED LIGHT METAL LEG SPECIALISTS.

More Desoutter Light Metal Legs are being supplied to-day than all other makes put together.

"Vide Extracts from the Report of the Ministry of Pensions Committee of Inquiry on Artificial Limbs reproduced below."

PRE-EMINENT TO-DAY.

"With regard to (*a*) the fitting of the metal bucket of the 'Desoutter' limb to the stump is a matter of personal skill and technical manipulation of the metal which is at present confined to one or two persons in Mr. Desoutter's own establishment in London."

"The Desoutter and/or other approved light metal limbs should be placed upon the Consolidated list, and should be made available for all new cases in which the surgeon recommends these on surgical or other grounds instead of the standard pattern wooden legs."

Please write for a Copy of the Report and full particulars of the Desoutter Leg.

7 Surgical Reasons why the Desoutter Leg is essential:

1. The patent vertical joint on pelvic band which allows free rotation of trunk of body.
2. The patent swivel stirrup on bucket by which the leg is supported centrally, and which allows perfect freedom for swinging the leg from side to side.
3. The hygienic perforated bucket finished in glazed enamel, ensuring health, coolness, and cleanliness for the stump.
4. Its lightness, demanding the minimum amount of energy from the wearer.
5. Its scientific design and construction, assuring the safety of the knee when walking.
6. The great personal care combined with our patented scientific method of fitting each leg.
7. Its perfect balance or distribution of weight—*i.e.*, the limb being very light below the knee joint greatly facilitates walking.

The lightest, strongest, and most comfortable leg made.

Average weight for above knee amputation 3½ lb.

For Difficult Feeding Cases

In difficult alimentation due to functional or organic derangements, Horlick's Malted Milk, being bland, soothing and well tolerated by the most sensitive stomachs, may be used under any conditions as an efficient nutrient, even in obstinate cases which do not respond to ordinary dietetic treatment. Complete in itself and needing neither additional milk nor cooking, it is ready in a moment by briskly stirring the powder in hot or cold water only.

The Fat Content of Trufood Corresponds to Human Milk

Human milk contains 3.2%-3.3% of fat. Mixed with water Trufood dissolves rapidly and completely, giving a solution in which there is 3.25% of butter-fat in a perfect state of emulsion. Left to stand, there is normal separation of cream, and not immediate formation of oily globules as with other milk foods. In this Trufood is unique. Homogeneous distribution ensures that the fat does not adhere to the sides of the bottle, but is actually taken into the child's system and later normally digested.

Samples adequate for full clinical trial post free on request.

Bovo-Lactin Preparations

THESE preparations were devised and elaborated by the late E. C. Hort, F.R.C.P., of Harley Street and The Lister Institute.

BOVO-LACTIN is a concentrated, easily assimilated and highly nourishing preparation consisting essentially of carefully calculated amounts of animal protein (in some instances ox plasma and powdered yolk of egg), hæmoglobin, milk solids and carbohydrates.

In order to meet the varying requirements for such a concentrated food in sickness and in health, BOVO-LACTIN is combined with various "vehicles" to form :

INVALID BOVO-LACTIN

A concentrated powder with a high protein content, forming the ideal dietary in acute illness. It may be given alone or with milk, wine or brandy according to the necessities of the case.

ANALYSIS

Protein	18·56%
Fat	8·05%
Ash	1·50%
Moisture ..	4·08%
Carbohydrates & Non. Nitro. Ext. Matters	67·81%
	100·00%

BOVO-LACTIN ESSENCE

Besides its high protein content is rich in Vitamin "B." It is admirably adapted for use both in sickness and in health for young and old alike.

ANALYSIS.

Protein	30·38%
Fat	0·16%
Ash	18·80%
Moisture ..	23·28%
Carbohydrates & Non. Nitro. Ext. Matters	27·38%
	100·00%

BOVO-LACTIN CHOCOLATE

A powerful energiser invaluable as a restorative in all debilitated conditions. Specially useful for children.

ONE LB. TIN CONTAINS

67½ grammes (2·37 oz.) of Bovo - Lactin combined with 385½ grammes (13·63 oz.) of the finest oatmeal.

These preparations are manufactured in the Company's laboratories under the strictest supervision. Constant Chemical and Bacteriological examinations of the various products are made to ensure absolute purity.

Our preparations can be seen and tested at Stands No. 129 and 130 at the London Medical Exhibition at The Central Hall, Westminster, October 1st to 5th 1923. A visit will be cordially appreciated and our representative will be in attendance to furnish the fullest information.

FOOD PRODUCTS, LTD.,

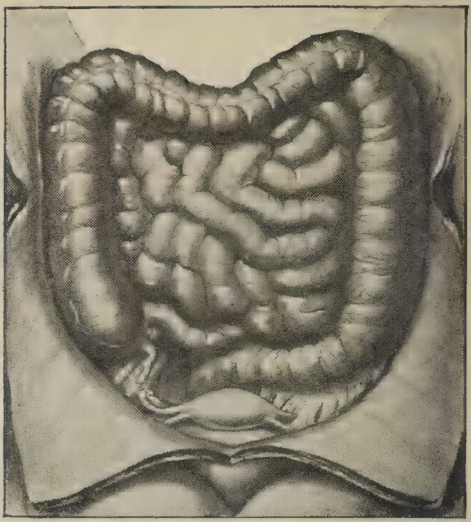
M.5

Spastic bowel; *(a)* showing ulcerations

Dyschezia due to fecal impaction



Atony due to sigmoidal adhesions

Lubrication Therapeusis

As you know, constipation usually follows an evolutionary course.

Atonic Constipation is characterised by a relaxed inactive gut favouring fecal impactions, particularly at the flexures of the intestine, and predisposing to inflammatory conditions, resulting in colitis. Nujol will prevent the formation of large fecal masses, thereby lessening bowel distention with its consequent inhibition of peristaltic nerve impulses.

Spastic Constipation is characterised by a narrow lumen with deep crypts, hypermotility and dry, hard, scybalous feces covered with mucus. Nujol lubricates the constricted canal, permeates the crypts, softens and coats the scybalous masses, thus relieving friction and consequent irritation.

In Dyschezia (rectal constipation) the feces may reach the pelvic colon in normal time, but the rectum is evacuated with much difficulty. The feces, by remaining too long in this region, have all the water abstracted, become hard and dry, and painful defecation ensues with resulting complications. Nujol keeps the fecal mass in this region soft and prevents complete water abstraction, thereby acting prophylactically against rectal diseases.

Nujol, the ideal lubricant, is thus the therapeutic common denominator of all types of constipation. Microscopic examinations show that too high a viscosity fails to permeate hardened scybala. Too low a viscosity tends to produce seepage. Exhaustive clinical tests show the viscosity of Nujol to be physiologically correct and in accord with the opinion of leading medical authorities.

Nujol

REG. U.S. PAT. OFF.

Products of *Proved* Efficacy

No. 1

"ROBOLEINE"
REGISTERED

TO add to the mass of testimony as to the merits of this grand reconstructive food, we have received a letter from the House Governor of the London Hospital. This is what he says: "The effect on some of our anæmic and rickety children has been MAGICAL".

CONSTITUENTS
Animal Fats, Maltose, Diastase and natural nitrogenous and phosphoric compounds, together with the Vitamins 'A', 'B' & 'C'.

FORMULA
Red Bone Marrow from the Long Bones of Oxen; Jelly from the Rib Bones; "Cream of Malt"; Egg Yolk (Lecithin); Neutralized Lemon Juice.

No. 2

"BI-PALATINOIDS"
REGISTERED

THE administration of Ferrous Carbonate in a nascent state hitherto has been a difficult—if not impossible—matter. Bi-Palatinoids solve it: they are gelatin capsules divided into two compartments; one contains the alkaline carbonate, and the other the iron sulphate. Not until the stomach is reached does the double reaction take place. Thus, nascent ferrous carbonate is formed in the ideal condition for assimilation.

CROOKES
COLLOSOLS

In General Debility, Wasting Diseases, the Anæmias, and the Convalescent Stages following exhausting illness.

COLLOSOL FERROMALT

(CROOKES)

Pure malt extract with colloidal iron, rich in protein, diastase and vitamines—the essentials for perfect carbohydrate metabolism. The iron in this preparation is in an extremely fine state of subdivision. Diffusion rapidly takes place over the whole of the stomach, and the known low chemical affinity of colloids prevents too rapid absorption of iron in individual positions.

Clinical experience has established the value of Collosol Ferromalt in all these conditions where a hæmatinic and nutritive tonic is indicated. It is non-irritant to the stomach, does not induce constipation or blacken the teeth.

Collosol Ferromalt (Crookes) merits thorough and extended trials at the hands of every practitioner.

AD 1715

PHYLLOSAN

AN ACTIVE CHLOROPHYLL PRODUCT FOR THE TREATMENT OF ANÆMIA, CHLOROSIS AND WASTING DISEASES, EXTREMELY VALUABLE IN CASES OF GENERAL DEBILITY AND CONVALESCENCE, PRODUCING A ROBORANT AND INVIGORATING EFFECT ON THE ENTIRE SYSTEM WITH A SURE AND PROFOUND INFLUENCE ON THE HÆMOGLOBIN CONTENT. FAR SUPERIOR TO AND MORE EFFICIENT THAN THERAPEUTICS OF IRON. EASILY ASSIMILATED BY THE MOST ENFEEBLED ORGANISM, NON-CONSTIPATING AND PLEASANT.

"PRACTITIONER" :—Its usefulness in anæmic and chlorotic conditions has been well established.

"PRESCRIBER" :—Phyllosan has been received with interest and enthusiasm . . . . has been well established . . . . one can see endless possibilities.

"MEDICAL PRESS AND CIRCULAR" :—Under the influence of Phyllosan the red blood cells increase, while the hæmoglobin content rapidly rise in cases which have failed to respond to iron."

"JOURNAL OF CLINICAL RESEARCH" :—Phyllosan can achieve results in Anæmia often better than those customarily obtained with iron preparations. Largely confirmed by recent observers.

"———— HOSPITAL, LONDON" :—Phyllosan has given excellent results, far superior to those obtained under orthodox methods.————, M.D., F.R.C.S.

PHYLLOSAN is supplied in tablet form, of 5 grs. each. Dosage: two tabs twice or three times daily, before meals.

The Proprietors will appreciate the privilege of sending any member of the Medical Profession or Hospitals SAMPLES sufficient for clinical observations, together with literature and clinical reports, free of charge.

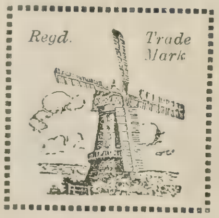
Professional pronouncements on the subject of bread

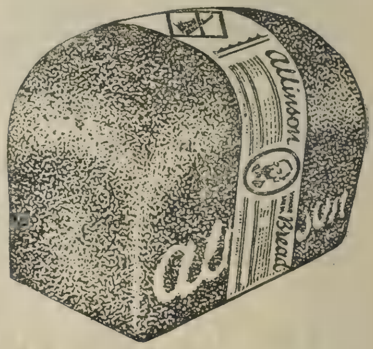
—never half-hearted—have recently been so frequent and forcible, that it would not seem an overstatement of the case to say that the medical profession is unanimous in its endorsement of wholemeal bread, particularly for invalids and children.



A word of caution in this connection may not be out of place. Not every brown bread is wholemeal; the one bread that has always been sold on its own merits as pure wholemeal—nothing added, nothing taken away—is Allinson—100% wheat. To identify the genuine Allinson Wholemeal Bread, see the paper band round the loaf.

If any difficulty is experienced in obtaining regular supplies please write for information to:

ALLINSON LTD. Cambridge Rd. London, E.2.



Allinson WHOLEMEAL Bread

BISMOLAN

For the Treatment of Hemorrhoids

1. Lubricate the rectal region prior to defecation, to protect the hemorrhoids from injury and infection.
2. Introduce an easily soluble suppository, to bring about deturgence and contraction of the rectal mucosa and the blood vessels.

These objects are effectively accomplished by BISMOLAN Preparations — BISMOLAN SUPPOSITORIES and BISMOLAN OINTMENT—which contain bismuth-oxychloride, eucain, menthol and suprarenin.

BISMOLAN Preparations are antiseptic, prevent the passage of infectious germs into the veins, contract the mucosa and blood vessels, cause the hemorrhoids to diminish in size, thereby avoiding the danger of bleeding.

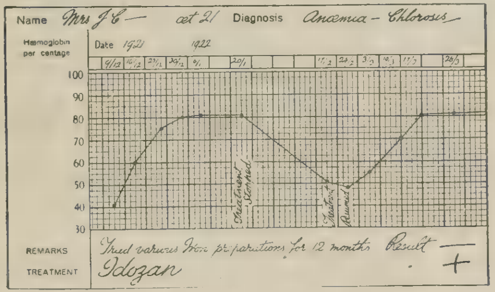
Report on

IDOZAN

The British Medical Journal. 9th Dec., 1922.

"Idozan is stated to be a neutral preparation, containing 5 per cent "of iron in a non-irritant form, which is readily dissociated to "liberate ionized iron. Our examination showed that Idozan had "a sweetish taste and did not produce any astringent effect in the "mouth, even when tasted undiluted. It was found to contain "5 per cent of iron in a non-ionized form, and ultra-filtration tests "showed that at least 97 per cent. of the iron was present in colloidal "form. Free iron is slowly released on warming with dilute acids, "and therefore the iron should leave the stomach in a form in which "it can be assimilated. Idozan is therefore a concentrated non-"irritant preparation of iron very suitable for therapeutic adminis-"tration, particularly when it is desired to give large doses of iron. "In the literature supplied interesting quotations are given from "Professor Poulsen and Dr. Lichtenstein, urging the importance of "intensive iron administration in cases of anæmia."

MORE CONVINCING THAN WORDS



Treatment started 9th December, 1921.

Suspended 20th January, 1922.

Resumed 24th February, 1922.

Further convincing graphs will be sent on application.

Idozan does not derange the stomach *or constipate*, for this reason it is suggested that it may be found useful for Nursing Mothers and Anæmia in Infants and Children; for as seems probable, according to "The Lancet," one frequent cause of the latter is iron starvation, and it would appear advisable to administer iron to all such cases at an early stage, whether or not other treatment is indicated.

Chalybeate Chocolate provides iron in the form of a delicious Sweetmeat, samples of which will be gladly sent on receipt of professional card.

GOLD MEDAL, INTERNATIONAL CONGRESS OF MEDICINE, LONDON, 1913.

MIST. HEPATICA CONC. (HEWLETT'S).

COMPOSITION.—Ext. Cascaræ, Ext. Rhei, Jalapin, Podophyllin, Cocainæ Hydrochlor., 1-20th gr. in each fluid drachm.

This preparation does NOT come under the Dangerous Drugs Act.

THIS excellent compound, first introduced as a general **aperient** and **cholagogue**, has now become a popular remedy, and attention has very recently been called to the value of the mixture, by various authorities, in that class of cases spoken of as Chronic Biliousness, in Catarrhal Jaundice, and in the Jaundice of simple Hepatic Torpor. **In passive or habitual Congestion of the Liver, so frequently met with, it has been used with marked benefit.**

In the treatment of acute or temporary constipation, frequently met with in the convalescence from acute disease, and in pregnancy, or in the constipation due to sedentary habits, to a deficiency of intestinal secretion and of peristalsis, the mixture can be prescribed with wonderful effect, positively curing cases that have resisted other remedies.

The dose is from 10 to 60 minims, according to the age and condition of the patient. One drachm is a direct aperient and is not accompanied by griping or tenesmus.

Packed for Dispensing only in 10-oz., 22-oz., 40-oz., and 90-oz. Bottles. Price in England, 12/6 per lb.

Please write: "Mist. Hepatica Conc. (HEWLETT'S)" to ensure obtaining this Preparation.

This preparation is also supplied "sine Cocaina," the dose and price remaining the same.

Syrup Phospho-Muriate of Quinine Co.

A RELIABLE TONIC. **Containing the Phosphates of Potassium, Calcium, Magnesium and Iron, with Quinine and Strychnine. Does not precipitate and is Acid in reaction and therefore more easily assimilated.**

Samples sent on application to—

THE CHARLES H. PHILLIPS CHEMICAL CO., 179, Acton Vale, W.3.

SULFARSENOL. **THE ARSENOBENZENE OF CHOICE IN THE TREATMENT OF SYPHILIS.**

(In use in the Civil and Military Hospitals in France.) Of all forms of Arsenobenzene **SULFARSENOL** is:

THE LEAST DANGEROUS because it is free from arsenoxide; because it is from 2 to 5 times less toxic than the other Arsenobenzenes.

THE MOST CONVENIENT because, being freely soluble, it may be injected intravenously, intramuscularly, or subcutaneously with equal satisfaction and without a special menstruum.

THE MOST EFFICACIOUS because the variety of its modes of administration permits of its application to the exigencies of each particular case, and renders possible the intensive treatment by cumulative doses which secures a therapeutic effect as rapid as it is thorough and permanent.

N.B.—**SULFARSENOL** has a specific action on the acute complications of Gonorrhœa: relief follows the first injection (18-24 centigr.), and subsidence without relapse in a few days.

LABORATORY of MEDICAL BIOCHEMISTRY, 36, Rue Claude-Lorrain, Paris (16).

A VALUABLE FOOD BISCUIT

MACFARLANE LANG & CO.'S
DINNER TOAST

The DINNER TOAST biscuit, the latest addition to our series of Food Biscuits, is composed of the finest wheaten flour, pure butter, malt and milk, contains but a trifling percentage of moisture, and makes a crisp, crusty appeal to the palate.

Primarily it has been introduced for persons of dyspeptic tendencies who cannot partake of ordinary bread or toast with comfort. For such, the DINNER TOAST BISCUIT, both from the standpoint of EASE OF DIGESTION AND HIGH CALORIC VALUE, provides an excellent substitute.

Taken also with a glass of milk, a cup of beef-tea or other nutritive fluid, the DINNER TOAST biscuit makes a sustaining emergency meal.

Send a postcard for Sample to

INFANT FOODS
—The Question of Starch.

Doctors, Nurses, Welfare Workers, &c., need have no fear that the presence of Starch detracts from the value of ROBINSON'S "Patent" BARLEY as a diluent of milk.

Analysis shows that the actual quantity of starch in Barley Water made from ROBINSON'S "Patent" BARLEY is only 0·552 per cent., when it is made according to directions. That is practically a negligible quantity.

ROBINSON'S
"Patent" BARLEY

When human milk is deficient, cow's milk (fresh, dried or condensed) diluted with Barley Water made from ROBINSON'S "Patent" BARLEY, is the nearest substitute for mother's milk.

100 Years' Reputation.

Lecturers in Operative Dental Surgery	W. E. Coe, L.D.S., D.M.D. John James, L.D.S.R.C.S. P. Lloyd Williams, M.R.C.S., L.D.S.
Lecturer in Preventive Dental Surgery	J. Sim Wallace, M.D., D.Sc., L.D.S.

A School of Dental Surgery will be opened at King's College Hospital early in the Autumn Session, in close connection with King's College, Strand, London, and the Medical School of King's College Hospital, at Denmark Hill.

The course of studies in Preliminary Science, Anatomy, Physiology, and Metallurgy is taken out at King's College; training in Dental Mechanics (Prosthetics), Operative Dental Surgery, General Medicine and Surgery, and Dental Hospital Practice at King's College Hospital and Medical School.

Complete training and tuition is provided, based on the requirements for the Diploma in Dental Surgery of the Royal College of Surgeons, for the Degree in Dental Surgery of the University of London, and for the Degrees and Diplomas of the various Universities and Licensing Corporations, and special arrangements have been made for those students desiring to obtain in addition a Medical qualification. A series of Post-graduate Courses will be announced shortly.

The number of students is strictly limited, and early application is desirable.

Full information may be obtained from the Secretary to the Medical School, S. C. RANNER, M.A., King's College Hospital Medical School, Denmark Hill, S.E. 5.

NURSING OR CONVALESCENT HOME, HOSPITAL OR INSTITUTION

A commanding modern building (formerly Rhos-on-Sea Preparatory School) is now at liberty. (VACANT POSSESSION.) It has 4,000 sq. yards of beautifully laid out grounds. The premises are admirably suitable for a Nursing or Convalescent Home, Hospital or Institution, or School.

Purchase money by instalments to suit purchaser, or by a Chief Rent, Debentures, or other first charge, saving Capital outlay, and preserving the benefit and goodwill.

Adjoining ripe building land, 23,500 sq. yards, can be had if desired. Highest medical Authorities state only one place in the British Isles equals Rhos-on-Sea from a health standard, and it is rapidly developing. Water supply from Lake Colwyn abundant and admirable. Town's gas, electric light and power available. Drainage passed as perfect.

The premises were let to a "Holiday Home Association" last vacation, and accommodated 80 Visitors plus Staff.

Within one mile Colwyn Bay Station (main line to Holyhead) and few yards from Electric Tram connecting Llandudno, etc.

Plans have been got out for additions.

For Plans and further particulars apply to **HARRY GOLDSMITH, Architect, Odstone, Rhos-on-Sea, Colwyn Bay.**

51, King St., MANCHESTER.

"ACOUSTIQUE" is the only aid in the deaf world wholeheartedly commended editorially by the Medical Press—the mouthpiece of the Medical Profession.

V.P.

PRINTED by HAZELL WATSON & VINEY, LD., 52, Long Acre, W.C.2, and PUBLISHED by the PROPRIETORS, WAKLEY & SON (1912), LTD. at No. 423, Strand, and No. 1, Bedford Street, Strand, in the County of London.—Saturday, Sept. 29, 1923.

A UNIQUE
"EVERY CONTINGENCY" INSURANCE

The ideal Insurance for professional men is one which covers (1) sickness of all kinds; (2) accidents of all kinds; (3) death, or survival to age 65. The Combined Policy of the Medical Sickness Assurance Society has been specially drawn up to provide for all of these contingencies—the rate charged is the lowest obtainable; the Society deals *only* with medical and dental practitioners; is mutual, and was established in 1884.

EXAMPLE:

At age 25 an annual premium of £25 1s. 8d. will ensure the following benefits—During incapacity from illness or accident, £7 7s. per week for first 26 weeks, and £3 13s. 6d. per week during remainder of illness to age 65. At age 65 or previous death, £700. Age 30 the premium is £29 0s. 5d.; age 35, £34 3s. 1d.; age 40, £41 4s. 10d.

The above Policy is entitled to share in bonus on Sickness and Life Assurance.

For full particulars write to the Secretary asking for Booklet "B."
